In certain types of acidosis in man (as in diabetes) there is, however, often enough hyperpnea to reduce the alveolar and arterial CO_2 tension to as little as a half or even a fourth of normal. This must mean that the respiratory center is being stimulated by something other than CO_2, for otherwise the hyperpnea would cease as soon as the CO_2 tension had been restored to normal. Until recently such a result would have been attributed to a direct stimulation of the respiratory neurons by hydrogen ions. The respiratory center was supposed to be so sensitive to the hydrogen ion that breathing would be markedly stimulated by increases in hydrion concentration too small to be detected by existing methods. Thus Haldane[67] (p. 185) calculated that the 1.5 mm. increase in arterial CO_2 tension that sufficed to double pulmonary ventilation in one of his subjects (see page 564) would mean a fall of only 0.012 in arterial pH (a change that is not detectible with certainty by any of the methods now in use) and that one-twentieth of this (a drop of pH 0.0006) would be enough to affect breathing quite definitely. As we have already seen (page 561), the careful experiments of Nielsen have shown clearly that the respiratory center of man is not nearly as sensitive to changes in hydrion concentration as this implies and have cast serious doubts upon the ability of the hydrogen ion per se to stimulate the center directly. It would seem that if the central neurons are directly affected by changes in hydrion concentration their sensitivity to that stimulus must vary enormously from time to time.

It is possible that the hyperpnea of acidosis (in so far as it cannot be ascribed to an increase in carbon dioxide tension in the center) is due entirely to reflexes from the carotid and aortic bodies, for these have recently (1939) been found to be aroused by changes in pH well within the limits that might be encountered clinically (page 588). Nielsen[118] found that the sensitivity of the respiratory center (estimated by its response to inhalation of 4 per cent carbon dioxide in air) was definitely increased in his subjects by acidosis. His conclusion was that the hyperpnea of acidosis is the result of the increased excitability of the center. Perhaps the increased excitability of the center noted by Nielsen is partly or even entirely due to the reflexes just alluded to. This would make it similar to the hyperpnea of anoxemia, which Nielsen (as well as many others) believed also to be due to increased excitability of the center to carbon dioxide, and which, as we shall see (page 587), is almost certainly due to reflexes from the carotid and aortic bodies. On the other hand, it is by no means certain that the respiratory neurons do not respond directly to changes in hydrion concentration, as they were for many years believed to do. The writer is following Krogh,[95] whose experience and wisdom in matters pertaining to respiration are preeminent, in believing that the center responds to carbon dioxide as such and not to the hydrogen ion, but this does not preclude all sensitivity to the latter. The subject needs reinvestigation in the light of these recent developments.

We arrive at the following conception of the chemical control of respiration: *Carbon dioxide—a normal product of aerobic metabolism, possessing the*

unique properties of being able to diffuse very readily through living membranes and of being excitant in low concentrations and depressant (narcotic) in larger amounts—is responsible for the regulation under all ordinary circumstances. It acts as such and not by virtue of the formation of carbonic acid and liberation from this of hydrogen ions. The number of CO_2 molecules within each cell of the center determines its activity (probably through some still obscure drug action that facilitates the oxidative or maintenance reactions within the cell) and this number is determined by the tension of the gas in the arterial blood (which is in equilibrium with that of the alveolar air). Reflexes from the carotid and aortic bodies may become strong enough to drive the center during asphyxia, anoxemia, or acidosis (page 594) and when this occurs the result is the same as though the center had become more sensitive to carbon dioxide. Actual changes in sensitivity probably occur however: in hibernation (in which breathing is very slow and shallow although blood CO_2 content is very high and blood acidity as great as pH 7.1[128]*) some such change is very evident, and it is probable that an equally marked but opposite change occurs during exercise, though this may be because of the impingement of a new or augmented nerve influence upon the reticular formation (see page 604). Whether chemical factors affect breathing by altering the resistance to conduction across synapses in the reticular formation (as suggested by Pitts) or by altering the excitability of the neurons of that formation, remains to be determined.*

CHAPTER XL

THE REFLEX REGULATION OF RESPIRATION

We have seen (page 556) that, according to recent investigations, the respiratory center does not act rhythmically because of some quality conferred upon it by chemical stimuli (as had been generally believed to be true), but is enabled to do so only because of nerve impulses which rhythmically exert an inhibitory effect upon it. This in itself is enough to indicate the importance of the reflex factor in respiratory control. Further evidence in that direction is the recent discovery that certain chemical factors (notably oxygen-lack and acid-excess), which for many years had been supposed to stimulate breathing by a direct effect upon the respiratory center, actually produce their effect by setting up stimulant reflexes from the carotid and aortic bodies (page 587). Finally, the fact that the most vigorous hyperpnea of which man is capable—that due to muscular exercise—is associated with no increase in any known chemical factor in the blood but is nevertheless much stronger than any hyperpnea that can be elicited simply by intentionally increasing the chemical stimulus (page 604), practically compels the conclusion that nervous factors are dominant over biochemical in respiratory control. These points have been alluded to more or less incidentally in the preceding chapter. It is now necessary to consider them more specifically.

According to information now available the most important reflex influences in respiratory control are those aroused in the lungs by their alternate inflation and deflation, and those which originate in the carotid and aortic reflex zones. These two are the only sets of reflexes that are known to be essential to the automatic control of pulmonary ventilation; as long as they are operating respiration retains its normal character and adaptability, but when either is removed the breathing suffers in some important respect. If Stella and Pitts are correct, the impulses carried to and from the pontine pneumotaxic center (page 555) deserve inclusion with those from the lungs as an essential factor in respiratory control. Other afferent impulses can also affect breathing; some of these effects are either incidental and seemingly purposeless (such as the respiratory effects of emotional disturbances, or of strong visual, auditory or tactile sensations) or else they are protective devices (such as the suspension of breathing during irritation of the nasal and pharyngeal endings of the trigeminal nerve, or the effort at expulsion of an irritant from the air passages by means of a cough or a sneeze). Afferent impulses are also undoubtedly aroused in the thoracic walls and the respiratory muscles, but there is as yet no compelling evidence that they play any essential part in the control of breathing. Reflexes from the muscles and tendons probably cause the hyperpnea of exercise (page 604).

RESPIRATORY REFLEXES FROM THE LUNGS (THE HERING-BREUER REFLEXES)

These are the reflexes set up by inflation and emptying of the lungs, first described by Hering and Breuer in 1868.[78] The afferent pathway is in the vagus; this fact was also discovered by Hering and Breuer, who thus called

attention for the first time to the importance of the vagus in the control of respiration. This subject was thoroughly explored by Head[73] who devised a method for recording contractions of a slip of the diaphragm in such a way that only active contractions of the muscle were recorded and it was possible to inflate and deflate the lungs without producing passive disturbances in the record. This can be done readily in the rabbit, though not in other laboratory animals.

Head found that when he occluded the trachea just at the end of a normal inspiration, the diaphragm relaxed and apnea resulted until the increasing asphyxia overcame the nervous inhibition; then an inspiratory effort ensued, but it differed from the normal movements in that it was more powerful and lasted longer (Fig. 220). When the trachea was closed at the end of expiration an inspiration followed at the normal time, but it was abnormally powerful and prolonged (Fig. 220). Evidently the degree of inflation of the lung produced by a normal inspiration is sufficient to inhibit the contraction of the diaphragm. When the lungs were artificially inflated to a greater extent than this a prolonged inhibition of the diaphragm ensued (Fig. 221), and the result was the same when hydrogen was used for the inflation, showing that over-ventilation of the

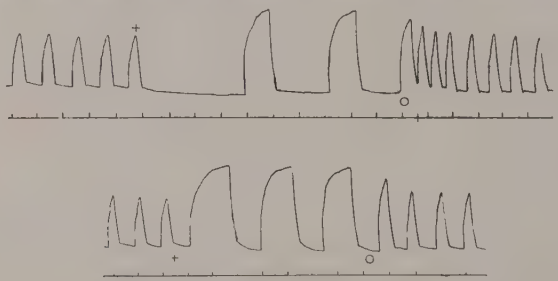

Fig. 220.—Hering-Breuer reflexes. Contraction of an isolated slip of the diaphragm (Head's method) in a rabbit.

Upper record:—occlusion of trachea (+) at end of a normal inspiration; note prolonged relaxation of the diaphragm, broken by two unusually marked and prolonged contractions; tracheal obstruction removed at (o).

Lower record:—occlusion of trachea (+) at end of a normal expiration: there is no pause, but succeeding inspiratory efforts are greatly increased in strength and duration; obstruction removed at (o). (From Head: J. Physiol. **10**: 1, 1889.)

alveoli was not responsible. If the lungs were made to collapse by allowing air to enter the chest, or by sucking air out of the trachea, the diaphragm underwent a prolonged tonic contraction (Fig. 221). By suction of air out of the lungs after a quiet inspiration it was possible to induce an inspiratory movement long before it would have occurred otherwise. All these phenomena were abolished when the vagus nerves were frozen, thus preventing them from carrying the essential afferent impulses. Breathing then became slower and the chest tended to assume the inspiratory position; after a time respiration became deeper again, but it continued to show inspiratory pauses and it remained slow (Fig. 222).

These results showed clearly, as indeed Hering and Breuer had already demonstrated, that inflation of the lungs inhibits inspiration and that collapse of the lungs stimulates it. This is the essence of the self-regulation (Selbststeuerung) of respiration by means of the vagus.

Since Head's time many other investigations have been made along these lines, but little of real importance was added to our knowledge about the influence of the vagus on respiration until quite recently. Stimulation of the central end of a cut vagus was employed by many workers as a means for determining the influence of the nerve on respiration, but the results were conflicting. As more is learned about the factors involved in such experiments it becomes increasingly evident that results of general applicability could never be obtained in that way. For one thing, it is now clear that the vagus trunk of a dog or cat contains at least three sets of nerve fibers that are capable of affecting respiration powerfully, these being: (1) the fibers mediating the two Hering-Breuer reflexes; (2) those representing the

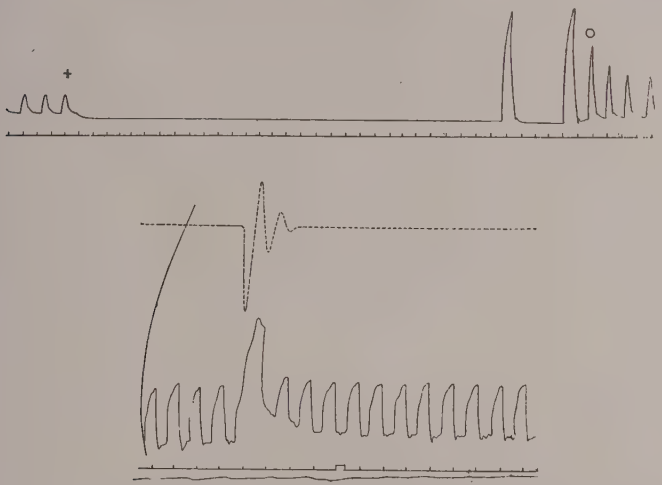

Fig. 221.—Hering-Breuer reflexes. Contraction of slip of diaphragm of rabbit as influenced by excessive inflation of lungs (upper record, + indicating inflation, o release) and by collapse of lungs (lower record, suction of air out of trachea at end of expiration, dotted line indicating change in intratracheal pressure). (From Head: J. Physiol. **10**: 1, 1889.)

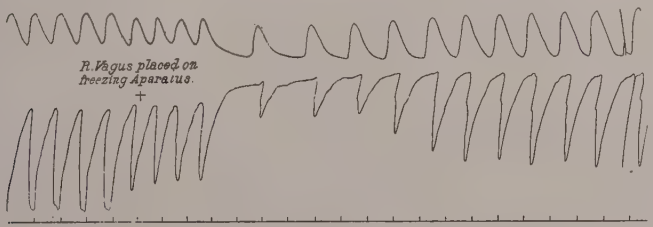

Fig. 222.—Effect of section of vagus nerve on respiration. Contractions of slip of diaphragm of rabbit (lower record) and changes in intratracheal pressure (upper record). Right vagus frozen (and thus inactivated without irritation); + indicates when nerve was placed on freezing apparatus. The left vagus had already been frozen. (From Head: J. Physiol. **10**: 1, 1889.)

sensory innervation of the trachea and bronchi, irritation of which causes a cough or at least active expiration; (3) the afferent fibers from the arch of the aorta and aortic body, stimulation of which may cause either inhibition of breathing and fall in blood pressure or hyperpnea and rise in blood pressure, depending upon the predominance of fibers from the pressoreceptors of the aortic arch or from the chemoreceptors of the aortic body (see page 569). Furthermore, differences in depth and type of anesthesia can greatly modify the results: under ether anesthesia it is very difficult to elicit respiratory inhibition in the

dog by stimulation of the vagus (or indeed of any afferent nerve), while under chloralose it is extremely easy to do so. Differences in the type of the stimulus may also modify the result; Hammouda and Wilson[69] noted that faradic current of a given strength when applied to a vagus of a dog at a rate of 50 per second caused apnea, but at a rate of 10 per second it caused acceleration of breathing. Differences in strength of the stimulus have long been known to have marked influence on the result. In the dog or cat fully (but not too deeply) anesthetized with chloralose or a barbiturate the tendency, in the writer's experience, is for the weakest effective stimulus to produce a decrease in breathing (either in rate or depth or both); a stronger current is likely to elicit expiratory contractions and may increase the rate of breathing; a very strong stimulus is again likely to be inhibitory. These results suggest that the inhibito-inspiratory (Hering-Breuer) fibers have the lowest threshold, the excito-inspiratory (Hering-Breuer) fibers the next (perhaps the fibers of the cough reflex also), while the fibers from the pressoreceptors of the aortic arch have the highest threshold and usually are dominant over the fibers from the chemoreceptors of the aortic body. It is obvious that the possibilities for obtaining useful results by electrical stimulation of a system as complicated and variable as this are poor indeed.

Recently new light has been cast on this subject, particularly by the work of Adrian,[2] who succeeded in reducing the vagus of the cat to a few fibers or even a single fiber carrying impulses from the lungs. By studying the action potentials in nerves thus simplified he was able to confirm most of Head's results and to add other data which now (in conjunction with the recent work of Pitts et al.) make it possible to form a reasonably clear picture of the part played by the Hering-Breuer reflexes in the control of respiration. This is as follows:—

The impulses are, of course, afferent.* They affect the inspiratory neurons predominantly and under ordinary circumstances perhaps exclusively. It may be that inspiration is inhibited by one set of impulses because they activate the "expiratory center" primarily (see page 557), but it is none the less fair to regard all of the important respiratory effects of these reflexes as being exerted on the inspiratory phase. Two distinct sets of nerve impulses are involved, one aroused by inflation of the lungs (inspiration), the other by deflation (expiration). The impulses aroused by inflation inhibit the inspiratory cells of the center, those aroused by deflation excite them. The inhibitory discharge occurs at every inspiration, and when the lungs are maintained in the inflated condition this discharge is continuous, showing that the receptors from which it arises are of the slowly adapting type. The excitatory discharge in the expiratory phase apparently does not occur during quiet breathing, but only when the lungs are emptied to a greater extent than under resting conditions; this can be accomplished in the experimental animal by pressure on the chest, by suction of air out of the trachea, or by pneumothorax, and probably also by active contraction of the expiratory muscles.† The receptors from which the impulses arise are located in the most distensible parts of the lungs, probably in the alveolar ducts (see page 547); the stimulus to the receptors is stretching. There are two sets of receptors, one for the inhibitory discharge,

*The only efferent fibers carried by the vagus to the respiratory structures below the larynx are those of the motor (constrictor) innervation of the bronchial muscle and possibly secretory fibers to the mucous glands of the bronchial passages. These are not directly concerned in the control of respiration, and the function of the vagus in this respect is entirely dependent upon afferent impulses carried by it to the respiratory neurons in the central nervous system.

†In Adrian's experiments there was probably more sustained activity of inspiration throughout the expiratory phase than is usual, for this is especially likely to occur in cats under chloralose anesthesia. One consequence of this would be less deflation of the lungs than normally. Adrian's conclusion—that the excito-inspiratory impulses are not set up under physiological conditions—may therefore be subject to modification. It is difficult to account for all of the Hering-Breuer phenomena on a basis of inhibito-inspiratory reflexes alone.

the other for the excitatory. The receptors are practically insensitive to changes in the composition of the air and are unaffected by air currents; their function is to signal the state of inflation of the lungs and nothing else. The inhibito-inspiratory receptors are the ones that normally keep the center informed about the volume of the lungs, and they are operative under all normal conditions. The excito-inspiratory receptors are brought into action only when deflation of the lungs is greater than it is under resting conditions.

The way in which the inhibito-inspiratory impulses affect breathing appears to be as follows: The many receptors from which they arise have different sensitivities to stretching; some are so sensitive that during quiet breathing they may continue to discharge impulses throughout the expiratory phase, and during inspiration the resulting inflation increases only the frequency of their discharge; others are inactive during expiration but their discharge begins with the onset of pulmonary expansion and becomes progressively more rapid until inspiration reaches its peak; others are still less sensitive to stretching, their activity beginning only at greater degrees of inflation. As a result of this organization, the inspiratory neurons of the center, as soon as they begin to discharge impulses to the inspiratory muscles, are subjected to an afferent influence which tends to stop their activity, and the degree of this inhibition is directly proportional to the degree of their activity (i.e., the depth of inspiration). The general arrangement is the same as that encountered elsewhere in the body (e.g., in the cardiovascular system) in that Nature seems to have developed an apparatus which is prone to overexert itself and which can survive only when this tendency is continually opposed. These inhibito-inspiratory impulses from stretch receptors in the lungs are the counterpart in the respiratory system of the impulses which are aroused by intravascular pressure in the carotid sinuses and aortic arch and which are indispensable to the normal control of blood pressure and heart rate (page 462).

On this basis it is easy to see why the inhibito-inspiratory impulses should check inspiration and thus lead to a smooth transition to expiration without a pause, but that (according to Adrian) is only a part of their function. They probably can also help to accelerate breathing, particularly when an increase in ventilation is needed, and the way they can do this is not as obvious as the above. According to Adrian, the nature of the effect of such impulses on the central neurons will depend upon whether the neurons are themselves discharging impulses or resting when the afferent inhibitory influence reaches them: in the former case the discharge will be curtailed and the resting period of the neurons will ensue more rapidly than it would otherwise, while in the latter case the same afferent influence will interfere with the processes of restitution. In the first case the expenditure of "active material" during the phase of activity would be diminished by the inhibitory influence and the interval required in preparation for a fresh burst of activity would be shortened; the rate of breathing, other things being equal, would therefore increase while the strength of each discharge to the respiratory muscles would not be diminished because the discharge preceded the inhibition. In the second case, however, an inhibitory influence upon the processes transpiring within nerve cells when they are not discharging impulses would delay removal of the ashes of previous activity and interfere with the building up of the state of unstable equilib-

rium requisite for a new burst of activity; the interval required for such processes would therefore be increased and the rate of breathing would be slowed (Fig. 223).

This general conception of a conserving and facilitating influence by inhibitory nerve impulses reaching an "all-or-none" tissue during its phase of activity, and of the opposite type of influence by the same impulses reaching the same tissue during its resting phase, has much to recommend it, and probably possesses wide applicability. It should be pointed out, however, that Adrian also concluded that the excito-inspiratory Hering-Breuer reflex is not a factor under ordinary circumstances, but this conclusion is by no means universally accepted, and further investigation is desirable to determine whether other animals or other anesthetics would make a difference in the results obtained. At present it seems to the writer that although only the inhibitory reflex is important during quiet breathing, the excitatory one can be brought into play by active contractions of the expiratory muscles. Thus during dyspnea both the factor postulated by Adrian and the additional one of direct excitation would cooperate to increase the rate of breathing. The way in which these factors cooperate with others in the normal control of breathing will be considered later.

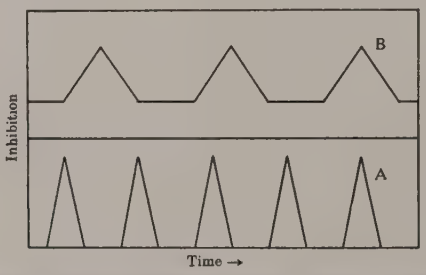

Fig. 223.—Diagram of Adrian's conception of the influence of afferent inhibitory vagus impulses on the rate of respiration. Abscissa = time; ordinate = number of inhibitory impulses per unit time. *A*, rapid development of high degree of inhibition with inspiration, none during expiration: this causes rapid breathing. *B*, slow increase in inhibition with inspiration, persistence of considerable inhibition during expiration: this causes slow breathing. (From Adrian: J. Physiol. 79: 332, 1933.)

When the vagus nerves are cut breathing characteristically becomes slower and deeper, the chest tends to assume a position of partial inspiration, and often there are pauses at the end of inspiration as well as expiration. In time, however, these effects tend to diminish; even in an hour or so in an acute experiment an animal's breathing may become normal again after vagotomy and it may show a normal type of increase in rate and depth when CO_2 is inhaled. Whether this means that other afferent impulses (notably the inhibito-inspiratory and excito-expiratory impulses from the pneumotaxic center, which also wax and wane in the rhythm of respiration) can completely take over the duties of the Hering-Breuer reflexes, is unknown. If the vagi are cut above the origin of the recurrent laryngeal nerves most of the muscles of the larynx will be paralyzed and the glottis will not open during inspiration as it normally does. This may interfere with the passage of air in and out of the lungs and tend to slow the breathing, but it is not a prominent factor. A tracheotomized animal shows practically the same respiratory effects as a normal one from

section of the vagus nerves. The dangers of vagotomy lie more in the abolition of the cough reflex, because of interruption of its afferent side, than in anything else.

RESPIRATORY REFLEXES FROM THE AORTA AND CAROTIDS

The Hering-Breuer reflexes undoubtedly play a large part in regulating the rate and depth of breathing under all ordinary circumstances, and this is readily understandable because they originate in receptors that are activated by the movements of the lungs. We now have to consider a set of respiratory reflexes which arise, not in the respiratory system, but in specialized receptors in close relation with the walls of certain major blood vessels—a location in which one scarcely expects to find elements of importance in the control of respiration. These are the afferent impulses from the stretch receptors (pressoreceptors) of the aortic arch and carotid sinuses, the importance of which in the control of blood pressure and heart rate has already been discussed (Chapter XXXIII), and from chemically sensitive nerve structures (chemoreceptors) located in the carotid and aortic bodies. The discovery of these reflexes —particularly those from the chemoreceptors—undoubtedly was one of the great events in respiratory physiology in recent years. The first of these to be discovered were the reflexes from the aortic region; this was done by J. F. and C. Heymans[82] in 1927. Almost simultaneously Danielopolu and his collaborators,[46] stimulated by the recent discovery of carotid sinus circulatory reflexes by H. E. Hering, reported reflexes from the carotid region similar in the main to those described by Heymans and Heymans in the aorta. C. Heymans and his collaborators, to satisfy themselves on these points, then began a series of experiments on carotid reflexes,[79-81] with the result not only of confirming the observations of Hering and of Danielopolu, but also of extending and adding to them so greatly as to constitute practically a new discovery, for which Heymans was awarded the Nobel Prize in Physiology for 1938. The results obtained by Heymans and his associates have been confirmed in the main by a number of different workers, but since this entire subject has developed in less than ten years it is not surprising that final answers to a number of the questions that were raised by his work are not yet available and that there should be some difference of opinion about several points of fundamental importance.

A brief summary of the undisputed facts about these reflexes is as follows: The respiratory reflexes arising in the aortic region are carried to the respiratory center by both *depressor* (aortic, Cyon) nerves, those arising in the carotids by both *sinus* (intercarotid, Hering) nerves. Reflexes originating in one of these regions are qualitatively identical with those from the other. The respiratory reflexes from the carotids are exaggerated by section of the depressor nerves and conversely; this is also true of the circulatory reflexes. Inactivation of one pair of these nerves may reduce but it will not abolish the respiratory effects of these reflexes in the intact animal. In the recent furore over carotid reflexes there has been a tendency to overlook this point and some of the discrepancies recorded in the literature are due to the mistaken assumption that all of the reflexes now under consideration emanate from the carotid reflex zone. The respiratory reflexes originating in each of these zones consist of two sets, one governed by pressure, the other by chemical influences, and

the effects of stimulation by these two means on the respiratory center (as on other medullary functions) are exactly opposite. *The receptors from which the pressure reflexes arise are anatomically distinct from those responsive to chemical changes, for the former are located in the adventitial coat of the carotid sinuses and aortic arch while the latter are localized in the carotid and aortic bodies. The pressure-sensitive receptors are unaffected by chemical factors and the chemosensitive receptors are unaffected by pressure changes.* The impulses from the two sets of receptors in each reflex zone are, however, carried over the*

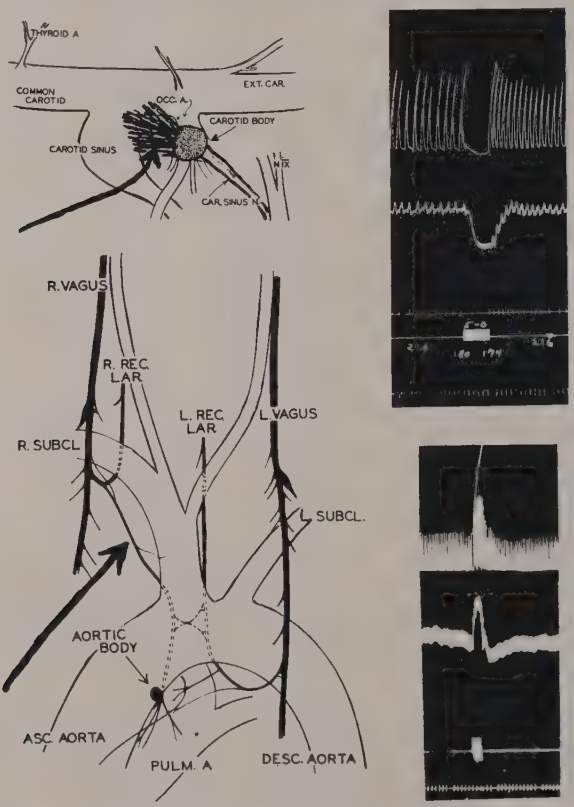

Fig. 224.—Effects of electrical stimulation of nerves from pressoreceptors and chemoreceptors in the dog.

Upper: Stimulation of fibers from pressoreceptors of carotid sinus at position indicated by arrow (between carotid sinus and carotid body). Tracing shows (from above down) respiration, arterial blood pressure, volume of expired air (in 500 ml.), signal, time in 5 second intervals. Note apnea, fall in blood pressure, and slowing of the heart (from 210 to 180-174) though both vagodepressor nerves were cut.

Lower: Stimulation of fibers from aortic body at point indicated by arrow (before they join other aortic afferents in region of left recurrent laryngeal nerve). Tracing arranged as above (record of volume of expired air omitted here). Note hyperpnea and rise in blood pressure though the vagodepressor nerves were intact. (Carotid reflex zones were denervated.) (From Schmidt: Anesthesia & Analgesia, **19**: 261, 1940.)

*Because of technical difficulties this has so far been proved only in the dog, but it is most probable that the anatomically similar structures in other animals have a similar specialization.

same nerve (sinus or depressor), section of which completely abolishes all reflex activity in that region.

Fig. 224 is a diagram of the various receptors and their innervation in the dog; it shows the points at which it is possible to stimulate nerve fibers carrying impulses from pressure receptors only (in the space between the carotid sinus and the carotid body) or from chemoreceptors only (between the aortic body and the junction of this nerve with the aortic trunk in the region of the right recurrent laryngeal). Typical results of faradic stimulation of these two nerves are also shown in Fig. 224. *It is evident that the effect of impulses from the pressure receptors on the respiratory center is inhibitory; since these impulses are also inhibitory to the vasomotor center one is justified in regarding them as characteristically depressant to medullary functions in general.* Stimulation of the nerve from the chemoreceptors, on the other hand, causes an increase of respiration and blood pressure; impulses from these structures may be regarded as stimulant to medullary functions in general.†* In fact in some instances strong stimulation of the chemoreceptors has been found to cause generalized motor activity throughout the central nervous system, even culminating in generalized convulsions, and these could be abolished instantly by removing the stimulus from the chemoreceptors.[138, 140]

Results similar to these have been obtained by a number of different investigators using more physiological stimuli. There can be no doubt that since the effects exerted on respiration by the two types of reflexes are in general exactly opposed and the stimuli which arouse them are totally different, the parts played by them in respiratory control must also be dissimilar.

Respiratory Reflexes From the Pressoreceptors in the Carotid Sinuses and Aortic Arch

As we have seen, these responses parallel the vasomotor reflexes: rise in pressure in the aorta or carotids tends reflexly to slow breathing and to lower the blood pressure, while fall in pressure in the same regions tends reflexly to increase both respiration and blood pressure. This can be shown conclusively by means of suitable crossed-circulation or perfusion experiments in which it is possible to alter at will the pressure in one of the reflex zones. Fig. 225 shows the results of such an experiment in the aortic region and Fig. 226 represents an analogous experiment on the carotid sinuses. In such cases rise in intravascular pressure regularly causes respiratory inhibition, and this is proved to be entirely reflex in origin because it no longer occurs after section or blocking of the corresponding nerves (aortic or sinus). Stimulation of respiration and circulation may occur when these inhibitory influences are suddenly withdrawn, either by reducing an abnormally high intravascular pressure (Fig. 226) or by denervating all of the reflex zones (Fig. 227), but stimulant effects from the pressure receptors always mean this negative type of stimulation, which is in sharp contrast with the positive stimulant influence

*It is true that these impulses also cause *increased* activity of the cardioinhibitory center but this may mean that their primary effect on the circulatory regulating centers is to inhibit the sympathetic parts of this system and thus, through a reciprocal innervation, to release the cardioinhibitory center from inhibitory control previously exerted on it by impulses from the cardioaccelerator center. Thus all of their effects could be attributed to a depression of medullary activity, but at present this is entirely hypothetical.

†Here the cardioinhibitory mechanism participates in the general medullary stimulation; at least this is true of the carotid body receptors of the dog, for intense reflex bradycardia occurs when they are strongly stimulated chemically.

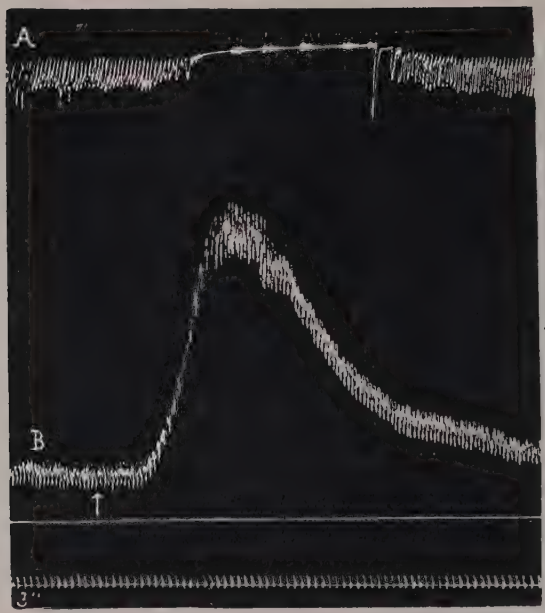

Fig. 225.—Reflex apnea due to rise in pressure in aorta. Dog: Respiratory movements (*A*) are movements of larynx of recipient animal whose head is completely separated from its trunk except for the vagodepressor nerves; the head is supplied with blood from a donor animal. Adrenalin injected into femoral vein of recipient dog; it could not affect movements of the head of this animal except through reflexes carried by the vagodepressor nerves. Blood pressure (*B*) in femoral artery of recipient dog. (From J. F. and C. Heymans: Arch. Internat. de Pharm. et Ther. **33**: 273, 1927.)

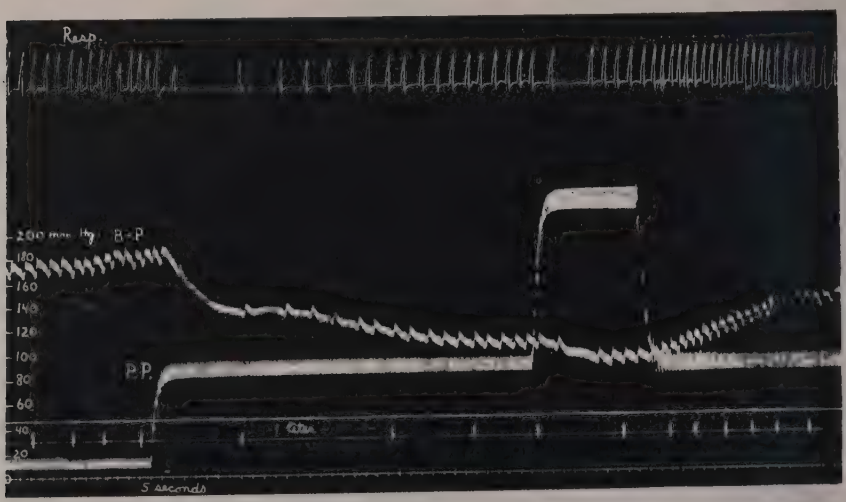

Fig. 226.—Reflex apnea due to rise in pressure in carotid sinuses. Perfusion of both sinuses of dog under barbital narcosis, vagodepressor nerves cut. Blood of donor (*A*) passes through carotids of recipient (*B*) without entering systemic circulation of *B*, since all branches of the carotids are tied. Effects of changes in pressure in carotids of *B* are due entirely to reflexes. *B-P* = blood pressure of recipient (*B*); *P.P.* = pressure in carotids of *B*; pressures recorded by mercury manometers, zero at time tracing, scale of pressure shown at left. Signal line shows volume of air breathed by dog (*B*), each mark representing 1 liter. (From Schmidt: Am. J. Physiol. **102**: 94, 1932.)

of the chemoreceptors. Furthermore, the hyperpnea which follows removal of pressoreceptor activity does not approach in intensity that which occurs when the chemoreceptors are stimulated.

Having thus identified these reflexes and learned the general nature of the effects which they can exert, we come to the question of their importance in the control of respiration. There can be no doubt that this is slight at best, and for practical purposes it is probably non-existent. The chief rôle of the reflexes from the pressoreceptors is to regulate blood pressure by inhibiting vasomotor activity and heart rate when arterial pressure tends to rise, by reducing these depressor influences when the pressure tends to fall; the respiratory effects are probably manifestations of a now useless survival in an air-breathing animal of an organization that may have had considerable importance in a water-breathing ancestral form (see page 598). Thus although prolonged or permanent hypertension ensues when the pressoreceptors are suddenly denervated, hyperpnea, when it occurs at all, is

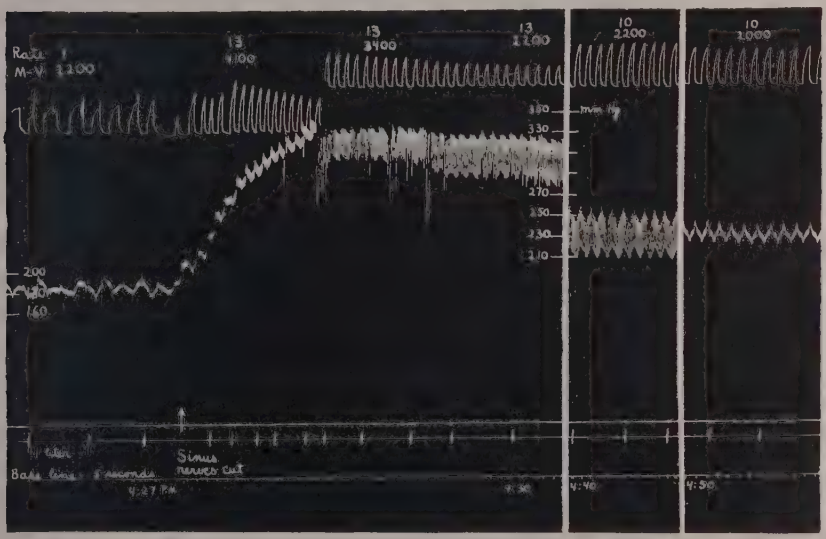

Fig. 227.—Effect of acute denervation of carotid sinuses and aorta. Dog: barbital narcosis; vagodepressor nerves cut. Sinus nerves divided at ↑. Note rise in blood pressure (scale shown) and increase in rate and depth of breathing (shown as Rate and M-V); cardiac arrhythmias also appeared. Subsequent tracings follow ten and twenty minutes later; respiration has recovered from the acute effects of the denervation but blood pressure remains high (about 240 mm.). (From Schmidt: Am. J. Physiol. **102**: 119, 1932.)

transitory (Fig. 227), as though any continuous inhibitory influence by these reflexes on the respiratory center could readily be dispensed with; this is definitely not the case with the vasomotor and cardioregulatory centers. The same conclusion can be derived from perfusion experiments: the changes in blood pressure produced reflexly by alterations in intracarotid and intraaortic pressure are proportional to, and last as long as the latter, but the respiratory effects are responses to a *change* in pressure rather than to any given pressure level and it is characteristic of them that they diminish or disappear when the pressure is maintained at the new point (Fig. 226). Some investigators have claimed that these pressure reflexes exert upon the respiratory center a tonic inhibitory influence comparable with that which they exert upon the vasomotor center, but this seems scarcely justified by existing evidence.

It has also been claimed that these reflexes are solely responsible for the respiratory effects of sudden changes in blood pressure. For many years it has been known that, in

laboratory animals suitably prepared, a sudden rise in blood pressure typically causes respiratory depression or, in favorable subjects, apnea (Fig. 228), and that a fall in pressure may elicit distinct hyperpnea (Fig. 229). Effects such as those shown in Fig. 228 have no clinical importance because the respiratory changes associated with abrupt increases in blood pressure in conscious subjects are dominated by psychic factors and are quite unlike those seen in anesthetized laboratory animals. The analogous effects of sudden marked decreases in blood pressure are so many and complex that the part played by one reflex influence cannot possibly be identified. The theoretical significance of these reactions is, however, considerable because we are dealing here with the relative importance of the two factors (nervous and chemical) which regulate the activity of nerve cells in

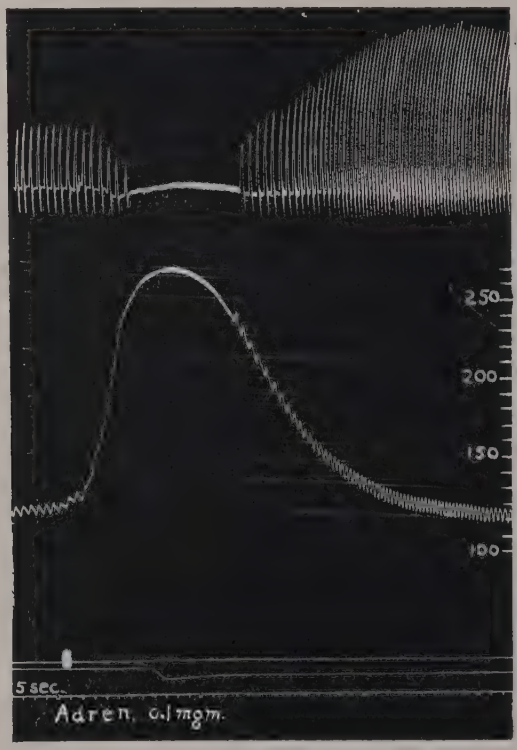

Fig. 228.—Respiratory depression (apnea) due to rise in blood pressure produced by adrenalin. Dog, barbital narcosis.

general, and this is one of the most important questions in all physiology. There is no doubt that reflexes from the pressoreceptors play a part, and probably a large one, in the respiratory effects of sudden changes in blood pressure in anesthetized or decerebrate animals and that previous to the work of Heymans this factor was entirely overlooked by physiologists. However, there is also no doubt that the reflexes are not the sole factor. Thus in animals whose sinus and depressor nerves have been cut drugs which raise blood pressure (as adrenalin) can still depress breathing and drugs which lower pressure can still stimulate it (Fig. 230). It is true that after the nerves are cut the respiratory effects of changes in blood pressure are decidedly less consistent than before (the reasons for this being still unknown), but the fact that respiration is affected at all indicates that some factor or factors other than these reflexes must be concerned. As far as we know at

present, the most important non-reflex factor is change in blood supply of the respiratory center, and this has been shown to be capable of influencing the activity of the center entirely apart from any known reflexes (Figs. 230 and 231). If the same sort of thing occurs in the intact animal (and there is no reason to believe that it does not) we must conclude that a change in blood pressure brings into simultaneous operation two factors which affect respiration in the same direction, and the end-result is the sum of their respective influences. These factors are reflexes from the pressure receptors of the carotids and aorta, and changes in the carbon dioxide tension within the cells of the respiratory center as a result of changes in their blood supply (see page 560). The extent to which the respiratory response to a change in blood pressure is due to either of these influences seems to depend largely on the conditions of the experiment and one factor of particular importance is the anesthetic. Since this raises a question which must always be taken into account in evaluating experimental results, namely, the validity of generalizations drawn from results obtained under one particular set of experimental conditions, it may be worth the reader's while to consider how the choice of the anesthetic can influence the results of experiments such as these.

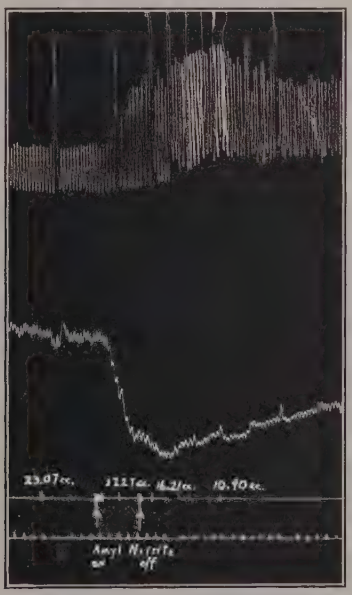

Fig. 229.—Respiratory stimulation due to fall in arterial pressure produced by amyl nitrite. Cat: barbital narcosis; vagus and sinus nerves intact. Figures above signal tracing indicate cerebral blood flow (venous outflow) in cubic centimeters per minute.

For experiments on carotid reflexes chloralose has come to be the preferred anesthetic because blood pressure then is higher and reflexes more active than is the case with other narcotics. This is true of both pressure and chemical reflex systems and it is only fair to point out that current ideas about these reflexes are bound up as intimately with the pharmacology of chloralose as the cholinergic conception of transmission of the nerve impulse is bound up with the pharmacology of eserine or prostigmine. Something is known about the latter but what chloralose does to the central nervous system in general and to these reflex systems in particular is quite unknown. This drug is unlike most of the so-called "indifferent narcotics" in that it can be injected rapidly into a vein without (as a rule) lowering blood pressure, and that spinal reflexes are definitely exaggerated by it; apparently it does not strongly narcotize the heart or the spinal cord and is not therefore an indifferent narcotic in the usual sense of the term. In decerebrate dogs and cats it can

be shown that chloralose frequently increases the sensitivity and the effectiveness of the carotid chemoreflex system;[139] a comparable effect on the pressoreceptors can also be demonstrated though less consistently. At the same time the effects of chemical influences directly on the cells of the center can be shown (by means of inhalations of carbon dioxide) to be diminished and occasionally they are practically abolished although the sensitivity and effectiveness of the chemoreflex system are greater than before. (This means, not that this anesthetic has depressed medullary functions less than most other drugs [which is the reason usually advanced for preferring it], but that it definitely exaggerates these reflex influences.) It is probable that under the influence of this drug breathing is influenced and maintained by reflexes to a greater extent than under any other anesthetic. At the same time blood pressure is high, perhaps abnormally so, and the cerebral blood vessels apparently are dilated by chloralose as by any narcotic; consequently the blood supply of the center is increased. But the metabolic activity of brain cells is decreased by narcotics in general, and there is no reason to regard chloralose as exceptional in this respect; the blood

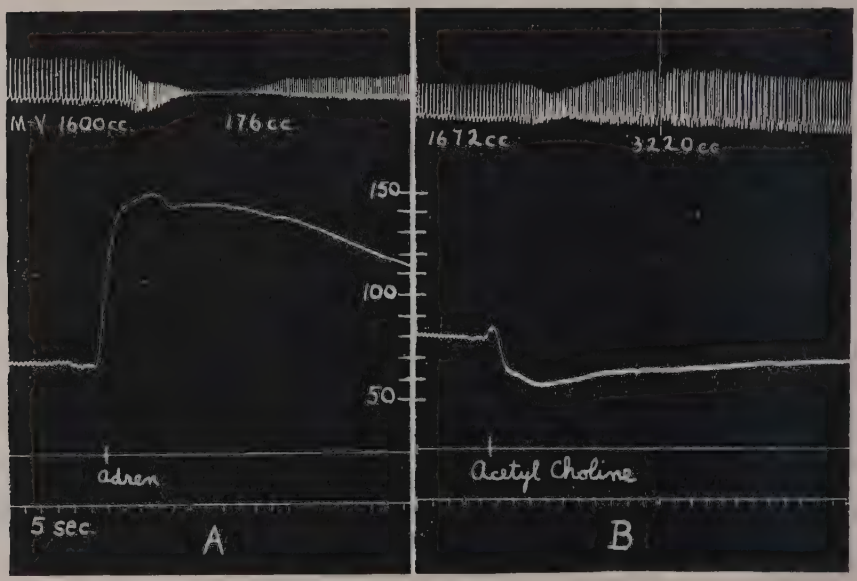

Fig. 230.—Respiratory effects of changes in blood pressure in an animal with depressor and sinus nerves cut. Rabbit: barbital narcosis. *A*, 0.05 mg. adrenalin intravenously; *B*, 0.005 mg. acetylcholine intravenously. Changes in minute volume of respiration: in *A*, from 1600 to 176 ml.; in *B*, from 1672 to 3220 c.c. (From Schmidt: Am. J. Physiol. **102**: 119, 1932.)

flow required to satisfy the needs of the cells of the center for a supply of oxygen and for removal of carbon dioxide would therefore be less than before. Since cerebral blood flow is actually increased by chloralose, the result is that the blood supply of the center is now out of all proportion to its requirements. Putting all these factors together—exaggeration of reflexes, reduced sensitivity to chemical influences, and excessive blood supply of the center—we find a situation in which the influence of alterations in cerebral blood flow is bound to be less important than that of reflexes, and experiments on animals under chloralose therefore give a distorted picture of the relative importance of the reflex and blood flow factors. Other anesthetics which do not exaggerate reflexes (as the barbiturates in dogs[139]), and do not cause an abnormally high blood pressure, obviate this difficulty to some extent, but even then the cerebral vessels are dilated and the metabolism of nerve cells is reduced, so that the blood supply of the center is probably in excess of its needs. In experiments in which the brain is artificially perfused (Fig. 231) the blood supply of the center can be

adjusted so that it is adequate but not excessive, and under such circumstances respiration responds to slight alterations in cerebral blood flow without the intervention of known reflexes. Even then the sensitivity is probably much less than that of the normal unnarcotized center.

It follows that the respiratory effects of changes in blood pressure are not due entirely to reflexes from the carotid and aortic pressoreceptors, as some have claimed.

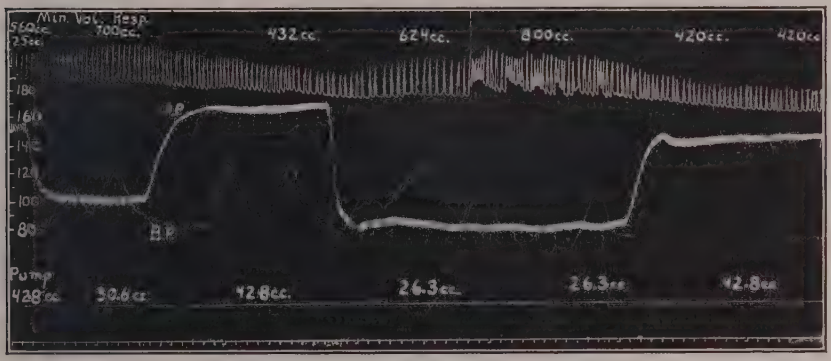

Fig. 231.—Respiratory effects of changes in cerebral blood flow after section of sinus and depressor nerves. Rabbit: anesthetized with barbital and heparinized; depressor and sinus nerves cut; respiration recorded by plethysmograph (minute volume given at top of tracing); blood pressure recorded from subclavian artery (*B.P.*); time in 5 second intervals. Cerebral circulation supplied with blood drawn from a subclavian artery and pumped through the internal carotids, both vertebral arteries being closed; *PP*, perfusion pressure; *Pump*, volume of blood pumped (per minute) through the brain. Note that respiration is depressed by an increase and stimulated by a decrease in cerebral blood flow.

Fig. 232.—Effects of external pressure on carotid sinus. Dog: chloralose anesthesia, depressor nerves cut, both sinus nerves intact. Left sinus compressed between thumb and finger at signal. Note fall in blood pressure and apnea.

Another claim for the importance of these reflexes is that they may be responsible for some cases of sudden respiratory failure during anesthesia with nitrous oxide. Downs[48] compiled a series of these unfortunate occurrences in man and adduced some experimental

evidence to indicate that under nitrous oxide-oxygen anesthesia the carotid pressoreceptors are abnormally sensitive to external pressure. He suggested that some sudden and unexplained fatalities under nitrous oxide-oxygen anesthesia might be due to mechanical stimulation of these receptors, either by operative manipulations in the region or by pressure by the thumbs of the anesthetist behind the angle of the jaw. The fall in blood pressure and inhibition of breathing that normally follow stimulation of these receptors might, he believes, be exaggerated sufficiently to cause death. It is true that the position of the pressoreceptors in the adventitial coat of the carotid sinus is such as to make them accessible to external pressure (Fig. 232) but it is probable that the most important factor in fatalities under nitrous oxide anesthesia is damage to the central nervous system by prolonged anoxemia (see Chapter XLV). Impulses from the pressoreceptors might well aggravate the situation by causing a fall in blood pressure, thus reducing further an already deficient oxygen supply to the central neurons and causing sudden and perhaps permanent failure of breathing.

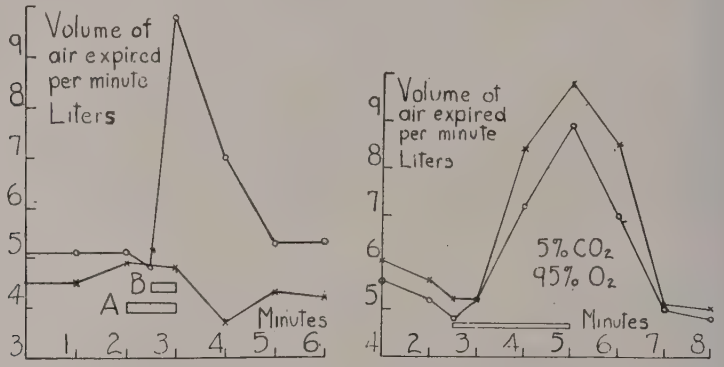

Fig. 233.—Effect of denervation of carotid sinuses on respiratory response of unanesthetized dog to inhalation of nitrogen and CO_2. Both experiments on the same animal.

On left:—nitrogen inhalation, —o— before denervation, —x— after denervation; *B*, duration of inhalation (thirty seconds) before denervation; *A*, duration of inhalation (one minute) after denervation. Note complete absence of respiratory response after denervation.

On right:—inhalation of 5 per cent CO_2 in oxygen for two and a half minutes, —o— before denervation, —x— after denervation. There is no significant difference after the denervation. (From Gemmill and Reeves: Am. J. Physiol. **105**: 487, 1933.)

RESPIRATORY REFLEXES FROM THE CHEMORECEPTORS

Impulses aroused in the carotid and aortic bodies by chemical agents are undoubtedly of fundamental importance to the control of respiration, and of much greater importance to this than to the control of the circulation; in both respects they are in sharp contrast with reflexes from the pressoreceptors. The chemoreceptors are activated by increase in the carbon dioxide tension or hydrion concentration or decrease in the oxygen tension in the fluid bathing them, and since these are precisely the blood changes which physiologists have for many years associated with the chemical control of respiration, it is not difficult to see why the discovery of these reflexes has necessitated considerable revision in respiratory physiology. Furthermore a number of drugs and poisons (lobeline, nicotine, cyanides, sulfides), which have long been known to stimulate breathing, have been found to owe these effects entirely to stimulation of the chemoreceptors and not—as previously supposed—of the respiratory center itself; thus a considerable amount of revision has been necessary in pharmacology. The reflex nature of these effects has been demonstrated in two general ways: first, by showing that they occur when the corresponding nerves

are intact but not when they are cut or otherwise inactivated (Fig. 233); second, by eliciting them in perfusion or crossed circulation experiments in which the exciting agents could act only on the carotid or aortic reflex zone and had no contact with other parts of the reacting animal (Fig. 234). In tests of the actions of drugs a variation of the first method was to inject a minute dose directly into the carotid or aorta so that the drug reached the corresponding chemoreceptors immediately and in concentration high enough to affect them but was ineffective elsewhere (Fig. 235). Still another variation was to use action potentials in the sinus nerve as the criterion of chemoreceptor activity.

The results obtained with these methods by various investigators have completely confirmed the observations originally made by Heymans and his collaborators in so far as the existence and general character of these reflexes are

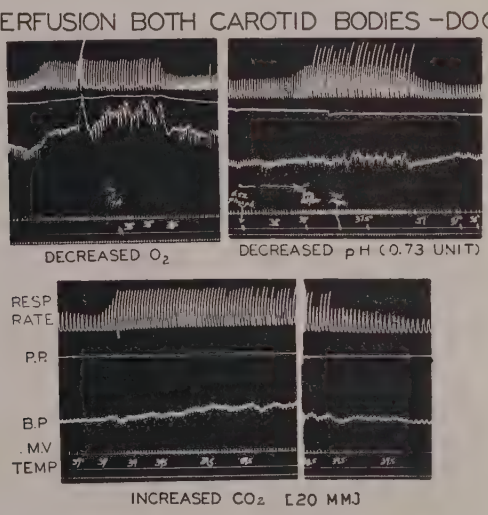

Fig. 234.—Carotid body reflexes in perfusion experiments.

Perfusion of both carotid bodies of dogs with modified Locke's solution. Each tracing shows (from above down) respiration (pneumogram), perfusion pressure (*PP*), femoral blood pressure (*BP*), volume of expired air (in 500 ml.), temperature of perfusing fluid, time in 5 second intervals. Vagodepressor nerves were cut in each case.

Decreased O_2-solution buffered with bicarbonate and CO_2 to pH 7.4 and freed of oxygen by bubbling nitrogen through it.

Decreased pH—solutions contained phosphate buffers—pH 7.25 and 6.52 respectively, both saturated with oxygen and free of CO_2.

Increased CO_2—solutions buffered with bicarbonate to pH 7.4 in both cases, CO_2 tension 0 and 20 mm. respectively. (All pH readings at 38° C.).

concerned. There is, however, some difference of opinion about their physiological significance. To obviate confusion in the reader's mind, it appears to be proper to give a conception of the physiological significance of these reflexes that seems to the writer to furnish the best fit with the available facts, while indicating, wherever that can be done, the points upon which opinions differ and the reasons therefor. The reader who is especially interested will find divergent opinions expressed in three recent review articles on the subject.[59, 80, 140]

The Part Played by Chemoreceptor Reflexes in the Control of Respiration.—It is generally agreed that the chemoreceptors can be stimulated by any or all of the three main chemical changes that occur in the blood during asphyxia or as the result of increased metabolic activity, i.e., decreased oxygen tension, increased carbon dioxide tension, and increased acidity. It is also generally agreed that at least one of these—carbon dioxide—acts upon the central neurons at the same time and in the same direction as on the chemoreceptors, and until recently it was almost universally believed that this is equally true of the other two factors. Consequently a change in respiratory activity associated with a change of any of these factors in the arterial blood might be due exclusively either to chemoreceptor reflexes, or to a direct effect on the center, or to some combination of the two. There are no distinguishing characteristics which enable one to decide which of the two influences is at work; the hyperpnea produced by chemoreceptor reflexes looks exactly like that due to

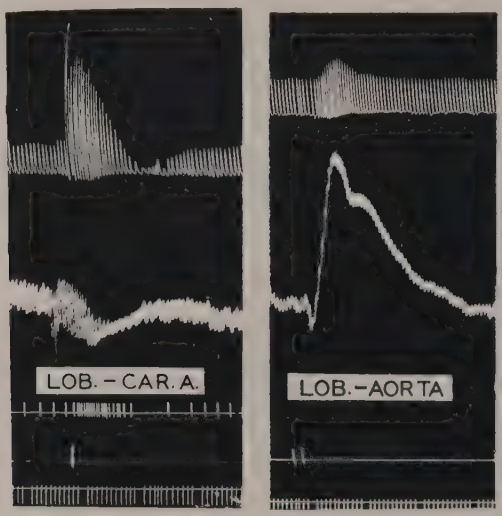

Fig. 235.—Chemoreceptor reflexes from intraarterial injections.

Experiments on dogs. Each tracing shows pneumogram (above), arterial blood pressure, and time in 5 second intervals; the one on the left also shows respiratory minute volume (in 500 ml.).

Left—all nerves intact; lobeline (0.1 mg.) injected into one common carotid through a needle tied into its superior thyroid branch: note hyperpnea (intense), bradycardia, and hypotension.

Right—carotid reflex zones denervated, vagodepressor nerves intact; lobeline (0.2 mg.) injected into aorta through small catheter whose tip lay just central to source of vessel supplying aortic body; note hyperpnea (relatively slight) and hypertension.

direct stimulation of the central neurons, for in each case an increase in depth of breathing is the characteristic result. Whatever differences there are between reflex and central responses to these factors must therefore be quantitative, having to do with such things as the relative sensitivity, power, speed of reaction, and ability to withstand adverse circumstances. The differences of opinion about the physiological significance of chemoreceptor reflexes arise from different interpretations of the validity of the experimental evidence.[140] In perusing the literature on this subject the reader will do well to remember

that the points to be decided are quantitative, not qualitative; much of the current confusion is due to the drawing of conclusions that should be based on strictly quantitative data from experimental observations that justify only qualitative deductions.

Oxygen Lack.—On this point there is less difference of opinion than on any other aspect of chemoreceptor activity, for it is now agreed almost universally that the hyperpnea (and hypertension) of anoxemia, no matter how produced, result from chemoreceptor reflexes and not from a direct effect upon the central neurons. One of the interesting and unanticipated consequences of this finding has been a new viewpoint on the therapy of mental disorders, especially schizophrenia, for, thanks to the discovery that in the absence of chemoreceptor reflexes anoxemia is purely depressant to respiration (and circulation), it is now believed that depression of cortical cells elicited by drastic interference with their metabolic processes (as by shock doses of insulin, convulsant doses of metrazol, repeated inhalations of nitrogen or injections of cyanide) may reduce to normal the exalted grade of neuronal activity which presumably was responsible for the disorder and thus produce a remission or even a cure. Since the ability of anoxia to depress the central neurons is unquestioned, it follows that the total respiratory response to anoxemia is the resultant of two opposing forces—a stimulant effect by the chemoreceptor reflexes, and a depression of the central neurons by anoxia. Whether there is any important direct stimulant effect by anoxia upon the center is not quite certain, though the burden of evidence seems to the writer to be against it;[140] Gesell,[62] who has been one of the chief advocates of central stimulation by anoxia, in his most recent expression of opinion of this subject admits that such an effect is either entirely absent or decidedly diminished under the influence of anesthesia, at least. We have already seen (page 566) that the central depression produced by anoxia may be responsible at least in part for the relative smallness of the anoxemic hyperpnea. The wide individual variations in the vigor of the response to anoxemia (page 566) could be attributed to variations in the resistance of the central neurons to the depressant effects, in the extent to which the centers are stimulated directly by anoxia, or in the intensity of the stimulant discharge from the chemoreceptors. There is at present no evidence on which to decide these questions but it seems to the writer that the physician will do well to forget about the possibility that anoxia can stimulate nerve cells and to regard it as essentially depressant to them. If there is any error in this view it will be on the safe side (see page 667).

When it comes to deciding whether chemoreceptor reflexes aroused by anoxia are a factor in maintaining respiratory activity under ordinary conditions, the evidence that this is not the case is overwhelming. The fact that the breathing of normal man is not depressed when he inhales air enriched with oxygen (page 566) shows clearly that the oxygen tension of his arterial blood under ordinary conditions (about 90 mm. Hg—see Chap. XLII) is not low enough to set up a measurable chemoreceptor reflex drive to respiration. Since the hyperpnea of anoxemia is generally conceded to be a chemoreceptor response, the order of magnitude of *the sensitivity of man's chemoreceptors to reduction in arterial oxygen tension is shown simply and decisively by determining the smallest degree of such reduction at which respiration is stimulated. This corresponds with a diminution of arterial oxygen tension from 90 mm. to 67 mm. Assuming 18 per cent oxygen in the inspired air to be the threshold for anoxemic hyperpnea, the corresponding figures for oxygen saturation of the arterial blood are about 95 per cent at 90 mm. tension, about 92 per cent at 67 mm.* (Fig. 249, page 566, the curve at 40 mm. CO_2 tension.) This is the greatest sensitivity to anoxemia that we have any right to expect in the chemoreceptors of man, and it is obvious that an effective anoxic stimulus is not going to be encountered as long as the oxygenation of the blood in the lungs is at all normal.* Once the threshold of this reflex system to anoxemia has been passed,

*This conclusion contradicts that derived by Euler, Liljestrand, and Zotterman[53] from recent experiments (on cats anesthetized with chloralose) in which they found signs of chemoreceptor activity as soon as the arterial oxygen saturation fell below 96 per cent. Gesell, Lapides, and Levin[62] also report observations indicating that chemoreceptor activity (in a vagotomized dog anesthetized with morphine and chloralose) was increased when the animal was made to breathe air containing practically a normal porportion (19.7 per cent) instead of a higher one (40 per cent) of oxygen. The reader must use his own judgment in evaluating the relative importance of these results as against the numerous observations on man to which allusion has just been made. Perhaps species differences are involved; perhaps the narcotic (chloralose) was responsible for the difference—a possibility which, in view of existing information about this drug (see page 581), deserves serious consideration. It may also be that, in the experiments of Euler *et al.*, the criterion of chemoreceptor activity (action potentials in the sinus nerve) was not as trustworthy as it was assumed to be (see Schmidt and Comroe[140] p. 143).

however, further decreases in oxygen tension lead to hyperpnea of progressively increasing intensity and with regard to *effectiveness,* this is the strongest chemoreceptor stimulant of any of the three chemical changes noted above, over the range that might be encountered in the arterial blood under conditions compatible with life. The *resistance* of these structures to adverse changes in their environment (which, as we shall see, is perhaps their most important physiological characteristic) is well shown by the fact that perfusion of the carotid bodies with fluid as nearly free of oxygen as it could be made causes only an intense hyperpnea that lasts as long as the perfusion is continued and leaves the receptors apparently undamaged (Fig. 236). The central neurons are depressed or paralyzed by relatively slight anoxia (Chap. XLV).

Hydrogen Ion Concentration.—We have already seen (page 561) that, according to recent evidence, the neurons of the center are much less sensitive and the chemoreceptors considerably more sensitive to this stimulus than had previously been supposed. It is

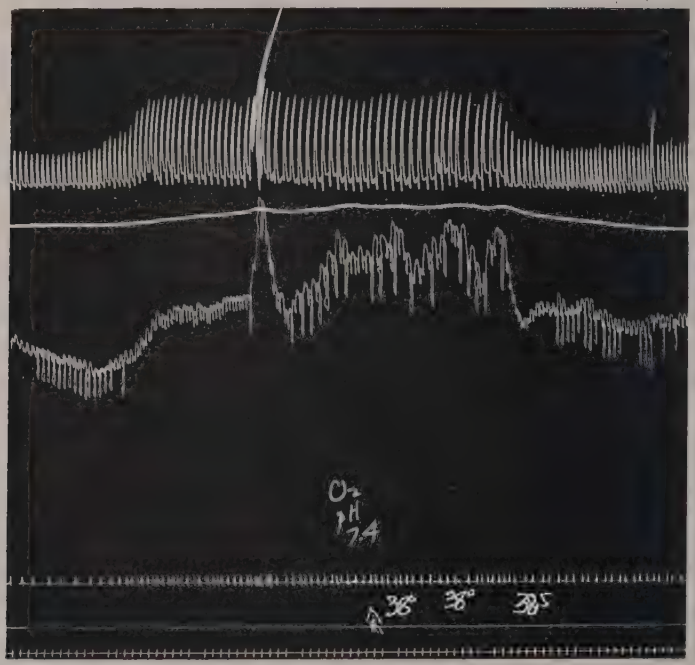

Fig. 236.—Absence of depression of chemoreceptors on perfusion with completely anoxic fluid. Upper record, respiratory movements; lower record, arterial pressure.

Perfusion of both carotid bodies of a vagotomized dog with Locke's fluid, freed of oxygen by bubbling nitrogen through it and buffered to pH 7.4 by bicarbonate equilibrated against a CO_2-N_2 mixture, instead of a similar fluid saturated with oxygen. Reflex hyperpnea and hypertension were undiminished after 4 minutes of this perfusion; on return to the oxygenated fluid, reflex effects promptly subsided. These effects could be elicited repeatedly without loss of reactivity. Nerve cells elsewhere would be inactivated by a briefer exposure to anoxia as nearly complete as this.

impossible at present to make any definite statement about the sensitivity of the center to the hydrogen ion. *The sensitivity of the chemoreceptors* has so far been investigated systematically only by one group (Fig. 237), who found that the smallest change in acidity that sufficed to elicit definite (though slight) reflex changes in respiration (in lightly anesthetized, vagotomized dogs whose carotid bodies were perfused with buffered saline solutions) corresponded with a shift of pH 0.1 in either direction. This is a relatively large shift to be associated with a minimal respiratory effect; inhalation of carbon dioxide

or muscular exercise would produce much greater hyperpneas with much smaller shifts in pH, indicating either that the chemoreceptors of man are much more sensitive than those of the dog or that chemoreceptor responses to changes in arterial pH per se are not likely to be a factor in respiratory control under any but very unusual conditions. The latter alternative appeals to the writer as the more probable, but this is a matter of opinion. In the animal experiments just alluded to larger increases in acidity produced more intense reflex hyperpneas and with shifts of the order of pH 0.5 or more, responses approaching those elicited by anoxemia or cyanide could be elicited consistently. Thus it is possible by existing evidence to account for the dyspnea of severe acidosis in man by strong stimulation of his chemoreceptors by means of the hydrogen ions themselves, and it is also possible that the central neurons are not directly stimulated by the hydrogen ion, but the reader should clearly understand that the latter remains to be proved. The resistance of the chemoreceptors to adverse circumstances was strikingly exhibited in the same experiments, for perfusion of the carotid bodies of dogs with Ringer's fluid as acid as pH 6.0 elicited only a strong reflex hyperpnea and apparently did not damage the reflex system.

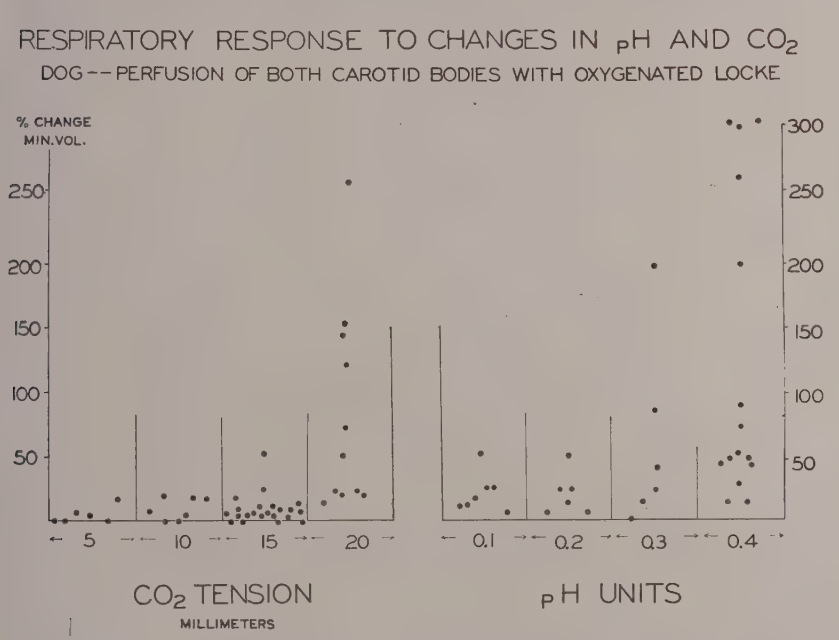

Fig. 237.—Each dot indicates one observation (on a vagotomized dog under light anesthesia by chloralose) when perfusion fluid was altered as indicated (i.e., when CO_2 tension was raised 5, 10, 15, or 20 mm. Hg, or when acidity was increased to the extent of a decrease of pH 0.1, 0.2, 0.3, or 0.4). Observations were made on 12 dogs all of which showed very strong reflex responses to perfusion with anoxic fluid. (From Proc. Soc. Exper. Biol. and Med. 42: 31, 1939.)

Carbon Dioxide.—It is on this point that the greatest difference of opinion exists; this (in the writer's opinion) is because carbon dioxide unquestionably owes an important part of its effects to an action directly on the central neurons and the disagreements have to do with the proportion of the effect due to this factor as compared with that attributable to the reflex component. There is no possibility here of ascribing an exclusive or even preponderant rôle to the chemoreceptors. On the other hand, all who have made pertinent observations agree that carbon dioxide can stimulate the chemoreceptors. Decision about the relative parts played by the reflexes and by direct effects on the central neurons in the respiratory response of an intact animal or man to changes in the carbon dioxide ten-

sion of the arterial blood must therefore rest entirely upon truly quantitative comparisons of sensitivity, power, speed and resistance.

As for *sensitivity*, in the only systematic investigation of this point now available (Fig. 237), the threshold (i.e, the smallest change in CO_2 tension in the fluid perfusing the carotid bodies to which there was a definite though slight respiratory response) of the chemoreceptors of lightly anesthetized, vagotomized dogs was found to be about 10 mm., while the corresponding threshold of the central neurons (i.e., the increase in arterial CO_2 tension at which hyperpnea began in the absence of chemoreflex activity) was in the vicinity of 3 mm.[143] These are the smallest changes in carbon dioxide tension to which the two systems have as yet been shown to respond in one species of animal (the dog) under comparable experimental conditions; whether they are applicable to other animals (including man) and other conditions is perhaps debatable, but these are the only figures now available for comparing the sensitivity of the two systems. Obviously they indicate the central neurons to be much the more sensitive.

The *speed* with which the chemoreceptors react to carbon dioxide was claimed[79] to be greater than that of the central neurons, but the only direct investigation of this point with methods capable of yielding the data required to settle it had an entirely negative outcome.[143] If (as all existing evidence indicates) the central neurons are more sensitive than the chemoreceptors to a rising carbon dioxide tension in the blood, any hyperpnea so produced in an intact animal would necessarily begin as a purely central response. Although it is possible to devise an experiment in which, by injection of solutions having a very high tension of CO_2 directly into the carotid, an instantaneous reflex hyperpnea can be elicited, this shows only that the chemoreceptors can be stimulated by carbon dioxide if the tension is high enough (which has not been denied); it does not warrant any deductions with respect to physiological importance.

The relative *power* of the central and reflex components of the response to carbon dioxide is shown very strikingly by an experimental observation that has often been made and never refuted, i.e., that the total increase in pulmonary ventilation produced by inhalation of carbon dioxide is just as great when chemoreceptor reflexes are inactive as when they are active (Fig. 233[125]). The situation here is obviously quite unlike that existing in anoxemia (Fig. 233), the hyperpnea of which is totally lacking in the absence of the reflexes. Although the CO_2 experiment does not necessarily prove that there is no reflex component at all in the response of the intact animal to this gas, it shows conclusively that the direct effect of CO_2 on the central neurons can be so strong that the reflex component can be withdrawn without its absence being noted.* Actual comparisons of the relative strengths of the reflex hyperpneas produced by carbon dioxide and other stimuli are few, but they are consistent in showing CO_2 to be much weaker than anoxemia in this respect.[140] This does not mean that chemoreceptor reflexes cannot be aroused by carbon dioxide, for all who have investigated the point agree that they can be. Under normal conditions the reflex component probably is unimportant, because the central neurons respond sooner and much more powerfully than the chemoreceptors and the latter come into play only when the central response cannot prevent a rise in arterial carbon dioxide tension sufficient to affect the relatively insensitive chemoreceptors. Under abnormal conditions in which the sensitivity of the central neurons to carbon dioxide is reduced, the chemoreceptor factor becomes much more important, as we shall see (page 594).

The *ruggedness* of the chemoreceptors (i.e., their ability to continue to function in the face of adverse conditions) is manifested again here: according to all who have made actual observations bearing on the point, these structures are not depressed but are only stimulated progressively by any increase in carbon dioxide tension to which they have so far been exposed. The fact that the respiratory response to rising carbon dioxide percentages in the inspired air does not increase steadily but reaches a maximum at a relatively low figure (9 per cent) and then declines (see page 565), must be attributed to the narcotic action of CO_2 upon the central neurons, not to decreased activity on the part of the chemoreceptors.

*This conclusion is supported by the experimental observations recently reported by Gesell, Lapides, and Levin,[62] who found that inactivation of the chemoreceptors during inhalation of a rather strong (6.5 per cent) mixture of CO_2 in oxygen had no measurable effect on respiration whereas similar inactivation produced distinct depression of breathing in the same animal when the CO_2 content of the inspired mixture was lower and the hyperpnea apparently was less intense.

Other Stimuli.—When the fluid perfusing the carotid bodies of anesthetized dogs is suddenly cooled, in a certain proportion of cases respiratory depression occurs, and when the fluid is again warmed hyperpnea sets in (Fig. 238); the effect can be proved to be reflex because it is abolished by inactivation of the sinus nerves. The most obvious explanation is that cooling inactivates the reflex system, but the situation is not so simple as this, as the following observations show: first, if cyanide is added to the perfusing fluid when the respiratory depression is at its height a reflex hyperpnea ensues—weaker perhaps than that elicited by the same dose at normal temperatures but none the less a real response; second, cooling of the perfusing medium may still cause depression of breathing and warming a hyperpnea, even though the fluid is a buffered saline mixture saturated with oxygen (tension more than 150 mm.), alkaline (pH 7.5), practically free of carbon dioxide (tension less than 1 mm.), and entirely free of any mysterious humoral material—in brief, when there is nothing to account for chemoreceptor activity that could be removed by cooling the fluid and thus cause respiratory depression. For these reasons it is permissible to suspect that the receptors responsible for these effects under such circumstances may not be activated by chemical factors in the blood but may be responding directly to the changes in temperature. Because the respiratory effects of even extreme changes in temperature are relatively slight at best, it is obvious that the number of temperature-sensitive receptors in the carotid bodies must be rather small, if indeed there are any at all.

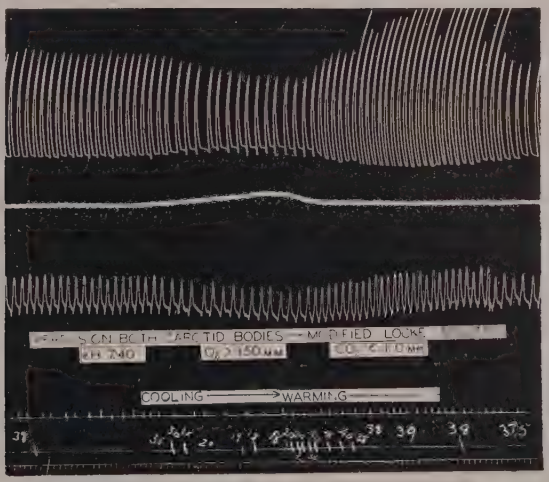

Fig. 238.—Effects of cooling and warming on chemoreceptors.
Perfusion of both carotid bodies (of a vagotomized dog lightly anesthetized with morphine and chloralose) with Locke's solution of pH 7.40, saturated with oxygen (tension above 150 mm. Hg) and free of CO_2 (tension less than 1 mm.). Note depression of breathing (minute volume shown in upper signal line, each stroke indicating 500 ml.) on cooling perfusing fluid from 38° to 18° C. and subsequent stimulation on warming fluid back to 38°. In other similar tests NaCN, injected into perfusing fluid when depression was at its greatest (temperature at its lowest) elicited a marked reflex hyperpnea.

The hyperpnea produced by a number of *drugs and poisons* (cyanide, sulfide, nicotine, lobeline, etc.), like that of anoxemia, is generally conceded to be due to chemoreceptor reflexes. Any direct effect that these substances exert on the central neurons appears to be purely depressant. The same statement can also be made about vasomotor stimulant effects from these drugs with the reservation that nicotine, lobeline, and other compounds that are capable of stimulating autonomic ganglia, can do this just as well without the chemoreceptors as with them; larger doses are, however, required than those that suffice to produce strong chemoreceptor stimulation, and the latter therefore accounts for the first effects (on circulation as well as respiration) of a rising concentration of any of these

substances in the blood. Very high concentrations of any effective stimulant to the chemoreceptors can also produce (through the carotid body of the dog) reflex stimulation of the cardioinhibitory center and thus prevent, or actually reverse, the rise in blood pressure that would otherwise result from the concomitant stimulation of the vasomotor center. This has no practical importance, for the requisite concentrations can be attained only by intravascular injections of large doses; its chief importance lies in its being an avoidable source of disagreement among different investigators of the influence of chemoreceptor reflexes upon the circulation.[39]

The list of chemicals that have been reported to be capable of stimulating the chemoreceptors is quite long, but it is probably significant that a considerable number of them can be gathered into two groups: first, those that would produce anoxia in the receptors either by interfering with the intracellular enzyme system (cyanides, sulfides) or by increasing the oxygen utilization (dinitrophenol, dinitrocresol); second those that have "nicotinic" properties (i.e., a stimulant, followed, in larger amounts, by a depressant action on autonomic ganglia, this group including nicotine, coniine, lobeline, hordenine, sparteine, and choline and its esters such as acetyl choline). A number of others, however, do not fall into either category (see Schmidt and Comroe[140] for a list of them), one of the outstanding instances being potassium salts. The latter have been found to depress the chemoreceptors (as well as the extremely resistant pressoreceptors) when the stimulant dose is exceeded or is frequently repeated, which makes it probable that this is a toxic action rather than an expression of a physiological rôle of potassium in the regulation of chemoreceptor activity. The latter conclusion probably applies also to acetyl choline, for the doses required to elicit chemoreceptor responses are relatively enormous.[140]

The Physiological Stimulus to the Chemoreceptors.—In the writer's opinion, existing information on this point warrants no conclusion more specific than that *these structures are so organized that they give rise to afferent impulses when their chemical equilibria are sufficiently disturbed, that suitable disturbances can probably be brought about in a number of different ways, and that among the agents capable of doing this are the three common chemical effects of metabolic activities, i.e., decreased oxygen tension, increased hydrion concentration, and increased carbon dioxide tension.* There may be some receptors here that respond to temperature changes *per se* and are not really chemoreceptors, but these are probably scanty and unimportant if present at all. There is at present no reason to believe that all chemoreceptor phenomena can be attributed to a common chemical change within them or that a specific chemical mediator is concerned in their activity. The only chemical stimulus to which both the chemoreceptors and the central neurons are known to respond actively is carbon dioxide and to this the center is much more sensitive than the chemoreceptors; carbon dioxide is also a relatively weak stimulus to the receptors. Oxygen-lack is the strongest physiological stimulus to these structures over the range compatible with life. Increased hydrion concentration can rival anoxemia as a stimulus but the changes necessary for maximal chemoreceptor activation are greater than pH 0.5 and are therefore not likely to be encountered in an intact animal or man.

Summary.—The part played by chemoreceptor reflexes in adjusting pulmonary ventilation to the requirements of the body must be negligible under normal conditions. This is indicated by the undoubted facts that the hyperpnea of exercise is not associated with any change in the blood that could stimulate these structures (page 604); that the hyperpnea of carbon dioxide inhalation has not been found to be modified in any measurable way by removing the chemoreceptor influence (page 590); and that oxygen inhalation does not depress the breathing of normal man (page 566). It has been claimed by some workers in this field that the chemoreceptors are continually stimulated by the carbon dioxide tension normally present in the arterial blood and that the reflex drive thus induced is a factor of importance in maintaining the activity of respiration even under resting conditions. Although this is undoubtedly true when the central neurons are severely depressed (see below) there is no valid evidence to indicate a similar relation when they are still highly reactive

to carbon dioxide; under the latter circumstances inactivation of the chemoreceptors often does not depress breathing at all, and when it does, the depression is slight and momentary.[143] In the writer's opinion, *the place of these reflexes in the body's economy lies, not in their sensitivity to the factors which (acting directly on the central neurons) normally regulate breathing, but in their ability to withstand, and to respond under, adverse circumstances which seriously interfere with the functional capacity of the central neurons. By virtue of this ruggedness the chemoreceptors are enabled to set up a powerful reflex drive and thus to maintain the activity of the neurons when the latter have lost their ability to respond to their normal stimuli.* It is not unlikely that other nerve tissues would be stimulated progressively as the chemoreceptors are when exposed to increasing anoxemia, acidosis and hypercapnia, if it were not for the fact that an excess of any of these stimuli decreases the ability of these more delicately organized tissues to function.

Table XIX summarizes existing information with regard to the threshold of the respiratory center and the chemoreceptors to decreased oxygen, increased carbon dioxide, and increased acidity. The figures are in each case the smallest that can be supported by actual experimental evidence. It is at once evident that the sensitivities of the two structures to these stimuli are utterly different. There is some reason to question the value of the CO_2 comparisons for here the sensitivity of the respiratory center of normal, unanesthetized man must be directly compared with that of the carotid bodies of dogs as determined by saline perfusions of the structures in anesthetized, vagotomized animals subjected of necessity to rather extensive operative procedures. It is wholly probable that the sensitivity of the chemoreceptors of man to carbon dioxide (and to the hydrogen ion) is greater than these figures indicate, but this is as yet undetermined; it is also (by existing methods) undeterminable. If we can judge from the threshold to anoxemia, the chemoreceptor thresholds ascertained in these animal experiments are not very different from those of intact normal man,[140] which indicates again the ruggedness of the reflex system. In any case, these are the only data now available for comparison. The size of the gap between the sensitivity of the chemoreceptors and that of the center is indicated more clearly when we compare these thresholds with data obtained from a normal man by analyses of blood collected by direct arterial and venous puncture (Table XX). If, when the subject was at rest, arterial blood were suddenly to be completely replaced by venous, the change would still be well below any known chemoreceptor threshold except for the diminution in oxygen tension. Even when the subject was exercising (on a stationary bicycle) and his pulmonary ventilation had increased seven-fold (which was the extent of the increase in oxygen consumption) the increase in carbon dioxide tension that would result from replacement of arterial by venous blood would be of an order that elicits only a weak stimulation of the carotid chemoreceptors in animal experiments and the increase in hydrion concentration would still be below any demonstrated chemoreceptor threshold.

TABLE XIX

SMALLEST CHANGE IN ARTERIAL BLOOD BY WHICH HYPERPNEA HAS BEEN PRODUCED

STIMULUS	KNOWN THRESHOLD OF RESP. CENTER OF MAN	KNOWN THRESHOLD OF CHEMORECEPTORS
Decreased O_2 tension	More than 23 mm. Hg*	23 mm. Hg (man-Ellis[52])
Increased CO_2 tension	0.075 mm. Hg*	10 mm. Hg (dog[142])
Decreased pH	?*	−0.1 (dog[142])

*These values are derived as follows:—The hyperpnea of anoxemia is assumed to begin as a reflex phenomenon in man as it has been shown to do in animals; the threshold of the respiratory center to anoxemia is therefore listed simply as being higher than that of the chemoreceptors. The threshold of the human respiratory center to carbon dioxide is calculated from the statement by Haldane[67] (page 185) that one-twentieth of the 1.5 mm. change that doubles pulmonary ventilation would affect breathing measurably. For reasons that have already been given (page 567), it is impossible at present to assign any definite value to the sensitivity of the respiratory center to the hydrogen ion.

TABLE XX

COMPOSITION OF ARTERIAL AND VENOUS BLOOD OF A NORMAL MAN AT REST AND DURING EXERCISE SEVERE ENOUGH TO INCREASE OXYGEN CONSUMPTION SEVEN-FOLD*

	AT REST (OXYGEN CONSUMPTION 250 ML. PER MINUTE)			EXERCISE (OXYGEN CONSUMPTION 1750 ML. PER MINUTE)		
	ARTERY	VEIN	A-V DIFFERENCE	ARTERY	VEIN	A-V DIFFERENCE
O_2 tension—mm.	78	40	38	75	31 ..	44
CO_2 tension—mm.	40	45.4	5.4	38	54.8	16.8
pH (serum)	7.425	7.399	0.026	7.351	7.278	0.073

Chemoreceptor Reflexes Under Abnormal Conditions

Under deep narcosis the situation described above may change greatly, but the result varies with different narcotics. Marshall and Rosenfeld[111] were the first to point this out; they found that phenobarbital and morphine brought about in dogs and cats a situation in which oxygen inhalation caused depression or failure of breathing while other drugs (chlorbutanol, urethane, paraldehyde and alcohol) did not. In animals given phenobarbital and morphine addition of carbon dioxide to the inspired oxygen did not prevent the occurrence of respiratory depression when oxygen was inhaled but after denervation of the carotids and aorta oxygen inhalation no longer caused depression of breathing. They concluded that under the influence of these drugs breathing is maintained—"almost if not entirely by the anoxemic stimulus acting through the sino-aortic mechanism." Their observations have been confirmed and the above interpretation is now generally accepted. It is interesting that ether appears to produce relatively greater depression of the response of the reflex system to anoxia than of that of the center to carbon dioxide while chloralose is perhaps most likely of all narcotics to swing the balance to the opposite extreme[139]—a point of importance in connection with the widespread use of chloralose in experiments intended to elucidate the physiology of chemoreceptor reflexes (see page 581).* The results obtained by stimulation or inactivation of the chemoreceptors thus appear to depend greatly upon the type of anesthesia as well as its depth, and it is probable that there are also species differences.

The reasons for these peculiar effects are still uncertain, but they become understandable if we recall that an excess of carbon dioxide is depressant to living cells in general and the cells of the respiratory center are exceptional only in that they happen to have the highly specialized property of being strongly stimulated by very small increases in the tension of this gas when they are normally reactive. When the cells are disorganized by narcosis, or anoxia, or both, they lose this specialized faculty more or less completely and then the depressant effect that is common to all living cells is the dominant or sole result of further increase in carbon dioxide tension. As we have seen (page 564) a great increase in carbon dioxide tension may depress the center even when it is normal. The chemoreceptors, however, appear to be made of sterner stuff: as far as existing information goes they are not appreciably depressed by any increase in carbon dioxide tension, but are only stimulated progressively as the stimulus is increased. The same is also true of their response to increased acidity and to decreased oxygen tension; both of these—particularly the latter—when carried beyond certain very narrow limits depress the activities of living tissues in general, but the chemoreceptors have not yet been shown to respond with anything but stimulation even to changes in these stimuli that would produce immediate failure of the center if they were elicited there (see page 592). Perhaps it is because the chemoreceptors can still set up a powerful drive to the respiratory center after the central neurons have ceased re-

*Gesell, Lapides, and Levin[62] have recently attributed to carbon dioxide an action essentially similar to that of ether, i.e., a progressive diminution of the effectiveness of the reflex influence as the tension of CO_2 in the blood increases. They reach this conclusion from the observation that (in a vagotomized dog narcotized with morphine and chloralose) inactivation of the chemoreceptors (by cooling of the nerves) caused less and less respiratory depression as the carbon dioxide content of the inspired air increased until finally no depression at all occurred at a CO_2 content of 6.5 per cent. Although an ether-like action by relatively high tensions of carbon dioxide is not unlikely in view of the well-known narcotic properties of this gas, it is possible to explain these observations on the very different basis (see page 590) that the central neurons were simply being stimulated maximally at the higher percentage of carbon dioxide.

sponding to anything else that a series of respiratory efforts are commonly seen a minute or so after the pulse has become imperceptible; these terminal efforts may be due to access of venous blood to the chemoreceptors. This indicates not only that the chemoreceptors can tolerate conditions that are rapidly fatal to the centers, but also that afferent impulses from the chemoreceptors can drive the cells of the center after the latter have ceased entirely to respond to changes in their immediate environment. To characterize this property the writer suggested a term which the older cardiac physiologists have applied to the Purkinje system in the heart (see Rothberger[136]), i.e., the *ultimum moriens,* as descriptive of the place of the chemoreceptors in the respiratory regulating system, meaning that it is the part of the system which is last to surrender its functions in the face of adverse circumstances.

SCHEMA SHOWING ROLES OF AORTIC AND CAROTID BODIES IN RESPIRATORY AND CIRCULATORY RESPONSE OF THE DOG TO ANOXIA

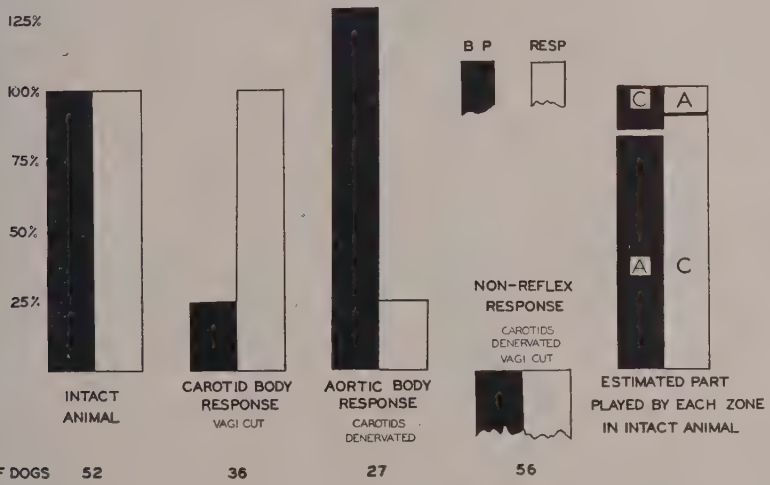

Fig. 239.—Schema showing rôles of aortic and carotid bodies in respiratory and circulatory response of the dog to anoxia. If the increase in respiration and blood pressure (B.P.) due to anoxia is regarded as 100 per cent for the intact dog, the *carotid* bodies alone are usually capable of producing *respiratory* stimulation equal to that of the entire dog (100 per cent), while the *aortic* area alone usually produces a rise *in B.P.* even greater than that in the intact animal (due to removal of carotid body reflex bradycardia and carotid sinus inhibition by complete carotid denervation). The last column is an estimate of the part played by carotid reflexes (C) and aortic reflexes (A) when both are functioning simultaneously. (From Comroe: Am. J. Physiol, 127: 176, 1939.)

Thus we can envisage the part played by these reflexes in respiratory control as that of furnishing a reflex drive to the center when the latter unaided is unable to prevent relatively marked and potentially dangerous changes in the chemical composition of the arterial blood. The conditions under which this is most likely to occur are: (1) anoxemia, no matter how produced; (2) addition of relatively high concentrations of carbon dioxide to the inspired air; (3) derangement of the reactivity of the center to changes in its environment, as by anoxia, trauma, disease, or particularly by narcotic drugs; (4) poisoning by metabolic acids (uncompensated acidosis) or by the drugs and poisons listed above as stimulants to the chemoreceptors, for all of these are likely to depress or paralyze the center apart from reflex stimulation.

Differences in the Total Chemoreceptor Activities of the Carotid and Aortic Regions.—So far we have made no effort to distinguish between the chemoreceptor reflexes from the two regions. As indicated above (page 576) they are qualitatively identical with one exception, which is the reflex cardiac inhibition that is aroused by strong stimulation of the carotid chemoreceptors of the dog; no comparable result is known to occur in that animal from stimulation of the aortic chemoreceptors; this reflex bradycardia is probably an experimental curiosity, elicited only by intravascular injections of large doses of certain drugs and therefore devoid of practical importance. There are wide individual variations in the partition of the remainder of the anoxic chemoreceptor response (hyperpnea and hypertension) between the two zones, but in a long series of observations on dogs Comroe[39] found an unmistakable tendency for the carotid reflexes to account for most of the hyperpnea, the aortic reflexes for most of the hypertension (Fig. 239). Some of the hypertension undoubtedly arises from stimulation of the carotid bodies and in the occasional dog vasomotor reflexes from these structures are quite marked, but in the average intact animal it seems clear that by far the largest part of the total hypertension produced by anoxemia is due to reflexes from the aortic chemoreceptors. In cats Comroe found the individual variations to be even wider than in dogs, but there was a definite tendency for the carotid chemoreceptors to account for more of the total hypertension and for the aortic structures to be responsible for a larger share of the total hyperpnea than was the case in the dog. In view of these species variations it is impossible to state anything definite about the probabilities in man.

The Significance of Respiratory Reflexes From the Carotids and Aorta.—The fact that respiration can be influenced profoundly by reflexes aroused in pressoreceptors and chemoreceptors that lie in no relation whatever with the ventilating surfaces but are actually (or practically) imbedded in the walls of major arteries is of itself remarkable. The inhibitory effect on respiration of increased activity of the pressoreceptors may be classed as a laboratory curiosity devoid of practical importance, but that cannot be said of the reflex hyperpnea (and hypertension) aroused by increased chemoreceptor activity, for, as noted above, such reflexes constitute an important factor in the body's defense against emergencies such as anoxemia, dangerously high concentrations of carbon dioxide in the inspired air, marked reduction in the sensitivity of the respiratory center to chemical stimuli, and poisoning by foreign chemicals and by products of the body's own metabolism. As far as anoxemia is concerned, chemoreceptor activity can fairly be regarded as the most important single item in the body's defense (see Chap. XLV) and it is not unlikely that many persons are alive today only because this activity was retained when narcotic drugs were given in large dosage. This is all the more remarkable when we consider that such reflexes do not play any comparable part (or indeed any demonstrable part at all) in the adjustment of pulmonary ventilation to changes in metabolic activity under ordinary circumstances such as muscular exercise (see page 593); they could be involved only when the exertion is so extreme that the blood becomes definitely more acid. Now it is unlikely that a reflex system such as this would be present so uniformly in animals whose ancestors were probably never exposed to anoxemia or poisoning by foreign chemicals and many of whom were never called upon for the extreme effort required to elicit an acid shift in the blood, if the system were not related to an organization that was of fundamental importance in some remote ancestral form and has been relegated to

a subordinate position by the development of the more sensitive and more highly specialized structures in the mammalian central nervous system. We have already seen that such a suggestion was first recorded by Marshall and Rosenfeld[111] who found that cats or dogs, when deeply poisoned by certain narcotics, are likely to cease breathing for long periods (sometimes permanently) if they are made to inhale oxygen, with or without carbon dioxide; since the phenomenon did not occur after denervation of the carotids and aorta, they concluded that breathing must have been maintained by reflexes aroused in those areas by anoxemia. They cite the experiments of Babák[9] who found that the respiratory movements of tadpoles are greatly influenced by changes in the oxygen tension of the environmental water but are affected little or not at all by changes in the carbon dioxide tension—a relationship very different from that existing in the mammalian respiratory center but very similar to that in the chemoreceptors. They suggested—"that when the mammalian organism is threatened with dissolution from respiratory failure it may adapt itself under certain conditions by reverting to a primitive type of respiratory control which seems to be normal for some of the lower vertebrates."

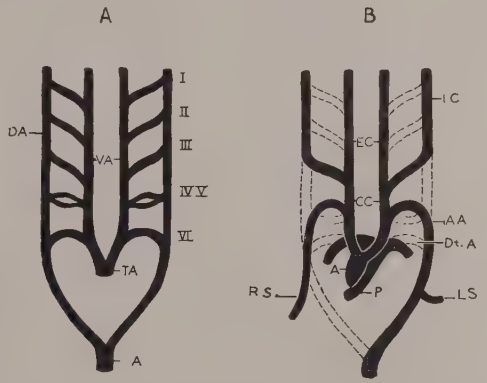

Fig. 240.—Diagram showing development of carotid sinuses and aortic arch from branchial arteries of embryo.

A, arrangement in embryo: primitive dorsal (*DA*) and ventral (*VA*) aortae and branchial arches (*I* to *VI*); *TA*, truncus arteriosus; *A*, unpaired dorsal aorta.

B, arrangement in adult: *IC*, internal carotid; *EC*, external carotid; *CC*, common carotid; *AA*, aortic arch; *DtA*, ductus arteriosus; *LS* and *RS*, subclavian arteries; *A*, aorta; *P*, pulmonary artery.

This suggestion, based on phylogenetic considerations, is rendered considerably more plausible as well as more attractive when ontogenetic factors are also taken into account. The carotid and aortic reflex systems in mammals are derived from the branchial arch system of the embryo and therefore they are related to a primitive organization for water-breathing (the gills). In the mammalian embryo the truncus arteriosus, arising from the aorta, divides into two ventral trunks in the neck and from each of these six branchial arch vessels arise, run dorsally and headward, and unite in two dorsal trunks which run back to the aorta (Fig. 240). As development proceeds the first and second branchial arch vessels of each side disappear; the ventral trunk in this vicinity gives rise to the external carotid, the dorsal trunk to the internal carotid. The third arch vessel on each side becomes the communication between the external and internal carotid, which corresponds with the carotid sinus in the adult. The fourth arch vessel on the left side becomes the aortic arch, while its mate becomes the right subclavian artery. The fifth pair fuse with the fourth at an early stage. The sixth give rise to the pulmonary artery.

The development of reflex systems in relation with the carotids and aorta appears to be connected with the early appearance of ectodermal nerve elements in proximity with the mesodermal cells from which the arterial walls are subsequently developed. In the third arch, elements from the glossopharyngeal nerve come into relation with mesoderm at an early stage (Boyd[29]) and it is probable that the chemoreceptors of the carotid body arise from the changes thus imposed on the two sets of cells; it is suggestive that muscle can be shown to be lacking in the occipital artery of the adult dog in the region of the carotid body but to be present just beyond the latter (Addison[1]), as though mesodermal material that should have formed muscle was diverted by the ectoderm of the developing glossopharyngeal nerve to form chemoreceptors. The aortic body (or bodies) probably have a similar origin from the mesoderm of the fourth arch and the ectoderm of the vagus nerves (Boyd). As for the pressoreceptors, their presence in the same regions as the chemoreceptors suggests a similar origin, and the lack of muscle coat in the carotid sinuses (Addison) may mean that here mesoderm had combined with embryonic neural elements to form pressoreceptors. If a lack of muscle in the coat of a major artery is always to be explained in this manner one would be entitled to suspect the presence of some special reflex system wherever such a lack exists, but why the fusion of mesodermal and ectodermal elements should form chemoreceptors in one case, pressoreceptors in another, remains unexplained, and it is unlikely (for reasons to be given immediately below) that receptors elsewhere would have functional significance similar to either of these.

For our present purpose the important point is that the chemoreflex and pressoreflex systems of the carotids and aorta can be related to the survival (in a relatively unaltered state) in the air-breathing terrestrial mammal of a system which would have had much more obvious significance in a water-breathing vertebrate. In the latter the branchial arteries persist, the peculiar capillary system characteristic of the gills is developed, and the whole structure is moved by muscles whose contraction is presided over and synchronized by the respiratory center in accordance with the requirements of the organism for a respiratory gas exchange. In such an animal a chemoreflex system capable of informing the respiratory center about changes in the aquatic environment would have obvious advantages. Furthermore, if some such system did exist it would be to the organism's advantage to have it regulated by changes in the tension of oxygen rather than carbon dioxide, for the latter is so soluble in water at ordinary temperatures that an increase in the tension of the gas would be unlikely to occur in water, as the result of stagnation or pollution, until the oxygen tension had been dangerously reduced. And since the main purpose of such a system would be to permit the organism to survive or escape from a noxious environment the reflexes should be both very resistant to depression by marked changes in the environmental fluid and capable of producing and maintaining a drive to the respiratory mechanism under circumstances to which the more highly differentiated nerve cells of the center would succumb if left to their own devices.

These are precisely the functional attributes which distinguish the chemoreceptors from the cells of the respiratory center of the air-breathing animal. In the development of such an animal the branchial arterial system never acquires a respiratory function and much of it becomes altered almost beyond recognition. It is probably significant, however, that the regions in which specialized reflexes appear and remain are also those in which the changes during development are least (Fig. 240); this suggests that the reflexes represent structures that are relatively primitive and undifferentiated. If we assume that the chemoreceptors subserve in the air-breathing animal the functions that they presumably would have subserved in the aquatic organism, granting that the environment of the receptors has become arterial blood instead of environmental water, we can account for most of their anatomical and physiological peculiarities. As for the pressoreceptors, there is as yet no evidence that corresponding structures in aquatic animals can give rise to reflex changes in the respiratory movements, but it is known[108] that in some such animals (the dogfish *Squalus acanthias* and the amphibian mud-puppy *Necturus maculosus*) the gills contain pressoreceptors that are capable of altering the heart rate reflexly. If this part of the carotid sinus pressure reflex can be aroused by changes in pressure in the gill arteries it is certainly not improbable that the rest of it can also. According to Krogh[95] gill breathing consumes an amount of energy which, compared with that in the air-breather, is relatively enormous in proportion to the amount of oxygen absorbed, and this sets limitations to the ability of such an animal to increase his metabolic activity; the fish is enabled to compensate for this, however, because he can secure a perfectly adequate gas exchange while swimming actively, simply by keeping

his mouth open and without any respiratory movements whatever. Perhaps inhibition of breathing and relaxation of the respiratory muscles on rise in pressure in the gill arteries are part of the organization for this. In the air-breathing mammal an arrangement such as this could never be advantageous; on the contrary it could be deleterious if it were sufficiently developed to lead to inhibition of respiratory movements whenever blood pressure rose, for the increased respiratory activity required during muscular exercise would thus be more or less completely prevented. Even under resting conditions the inhibition of the vasomotor center brought about by the increased pressoreceptor activity resulting from a rise in blood pressure would be opposed by an increase in the chemical stimulus to the same center in consequence of inhibition of respiration. Thus it is fortunate that the pressure reflexes have assumed as their principal function the regulation of blood pressure and heart rate and that respiratory effects from them are demonstrable only under special circumstances in the laboratory.

Protective Reflexes.—In this category we may consider a group of coordinated, purposeful responses to the inhalation of irritant materials. A *sneeze* is elicited by irritation of the mucous membrane of the nose, a *cough* by irritation of the respiratory passages beyond the nose. The impulses responsible for a sneeze are set up by irritation of sensory receptors of the trigeminal nerves and probably also by stimulation of the olfactory end-organs, while those which lead to a cough arise in the pharyngeal distribution of the glossopharyngeal and in the sensory endings of the vagus in the larynx, trachea, and bronchi. Both reflexes are characterized by a deep inspiration and a violent expiration; in a cough the vocal cords close completely when the inspiration is completed and do not open until the expiratory movement is well under way, so that the outward movement of air is an explosive one. It is interesting to note that once the deep inspiration has been made the violent contraction of the expiratory muscles is harder to control than if the inspiration is voluntarily kept shallow. Perhaps this is another instance of the interaction of the Hering-Breuer reflex and the reciprocal innervation of the inspiratory neurons (see page 557). The unusually complete reflex inhibition of the inspiratory neurons which follows a deep inspiration may automatically cause the forced expiration because it releases the expiratory neurons from the inhibition which the inspiratory cells ordinarily exert upon them.

These responses to inhalation of irritant material are considerably modified during anesthesia and probably also when the individual is unconscious for other reasons. Irritation of the upper air passages now causes apnea in the relaxed position (passive expiration). This part of the reflex is actually present in the conscious subject, but it is overshadowed by violent expiratory efforts which may be completely absent in the unconscious state. In the rabbit the inhibitory reflex is so powerful that intense irritation of the upper air passages may if continued cause fatal asphyxia, but this could not occur in most other animals or in man. This reflex is entirely abolished by anesthesia deep enough to remove the tendon and ocular reflexes; it operates in the early stages of inhalation of irritant anesthetic vapors but not in the stage of complete anesthesia. The reflex which causes a cough in the conscious subject takes the form of active expirations in the unconscious or anesthetized individual. As a result respiration is accelerated and it may also be increased in depth. Unlike the upper respiratory reflex, this continues to be active throughout the safe range of anesthesia. When it disappears respiration becomes slow and shallow and soon ceases entirely. It is undoubtedly a large factor in the relative safety of ether as an anesthetic, for this substance is more irritant than any of the other anesthetics that are commonly given by inhalation; by reason of this fact respiration is driven by reflexes from the lower respiratory passages and the depression of the center which ether produces is effectively counteracted. Substitution of a less irritant vapor, such as chloroform, removes the reflex stimulation while retaining the central depression. Such substitution is therefore a dangerous thing when the subject is already under anesthesia by ether.

Irritation of the larynx may cause spasm of the glottis, and irritation of the lower passages may lead to spasm of the bronchial muscle. These effects are likely to follow exposure to violent irritants, such as the poison gases used in modern warfare. They may also be encountered in civilian life, for some of the mechanical refrigerators now in use contain ammonia or sulfur dioxide, and sudden escape of these agents may produce all of the phenomena just mentioned. Such effects are probably due to actual damage to nerve endings and not to stimulation of specialized sensory receptors. They do not disappear as soon as the noxious agent is removed.

Other Reflexes.—Impulses carried through the *stellate ganglia* are said by Cromer and Ivy[43] to be important in the regulation of breathing, for after removal of the ganglia strong stimulation of the central end of a vagus nerve may cause a fatal apnea in dogs. This does not occur if the stellate ganglia are intact, for breathing then escapes from the inhibition produced by vagus stimulation before death occurs. The nature of this influence and its significance in the control of respiration have not yet been made evident.

Pain causes respiratory stimulation, but this is probably only because it sets up a generalized excitation which happens to include the respiratory neurons. The same statement is equally applicable to the respiratory changes associated with emotional disturbances and with unusual visual, auditory, and tactile sensations. These effects are only complications when respiration is normal, but they may be important under special circumstances. Advantage is taken of the respiratory stimulant effect of pain in the common procedure of spanking a newborn child to make it breathe, and sensations of cold aroused by the infant's sudden change in environment doubtless also play a part in arousing the center to activity. The practice of dashing cold water on the skin and of slapping the hands or pinching the cheeks of one who has lost consciousness rests on the same basis. In all probability the beneficial effects of inhalation of ammonia ("smelling salts"), the swallowing of irritants (whisky or brandy, aromatic spirits), or of hypodermic injection of irritants (camphor, ether, alcohol) are also due to reflexes of this same type.

Prolonged and severe pain may also cause sufficient increase in breathing to lead to acapnia (deficiency of CO_2 in the blood). If now the pain is suddenly relieved, as by anesthesia, breathing may cease because the reflex influence which had been maintaining it at a high level is removed and the chemical stimulus to the center is insufficient to keep it active without the reflex. Henderson and Scarbrough[76] called attention to this as a cause of sudden death during anesthesia. The same reasoning can be applied to excitatory respiratory reflexes in general. When the respiratory center is depressed by trauma, circulatory disturbances, or drugs, it becomes less responsive to all sorts of stimuli, and a point may be reached at which it continues to function only because afferent impulses and chemical stimuli together are just able to arouse the sluggish neurons to activity. If now an important group of afferent impulses is suddenly cut off—as by section of the vagus or sinus nerves, or deeper anesthesia—breathing may stop entirely.

Reflexes from contracting muscles probably are responsible for the hyperpnea of muscular exercise. As we shall see (page 604) this is the most vigorous hyperpnea of which man is capable, so that the importance of a reflex factor such as this must be rated correspondingly.

CHAPTER XLI

THE INTERPLAY BETWEEN NERVOUS AND CHEMICAL FACTORS IN THE REGULATION OF RESPIRATION

The course of events in the respiratory center during quiet breathing appears to be as follows: in the interval following the preceding discharge the inspiratory cells of the center, by reason of the oxidative reactions occurring within them, become progressively more excitable until the equilibrium in one or more of them becomes too unstable to be maintained any longer, and when it topples a burst of impulses results. These impulses spread through the reticular formation and all of the cells that are sufficiently excitable (unstable), or are adequately affected, respond to this disturbance by also discharging bursts over their axons. Thus the diaphragm, external intercostals, abductors of the vocal cords, and any other muscles that are involved in quiet breathing, are activated simultaneously, and by each axon leading from the medullary center a number of anterior horn cells may be activated—a "high step-up ratio" (Gesell). All this could be brought about by the discharge from a single reticular cell, and the pace for the entire system (i.e., the *rate* of breathing) could be set by that cell (or group of cells) which most rapidly attains the excitability requisite for a spontaneous discharge of impulses under resting conditions.

The chemical stimulus (which—following Krogh[95]—we shall identify as carbon dioxide acting as such—page 561) presumably acts as a stimulant drug would, namely by combining with the protoplasm of the central neurons in some way which furthers the intracellular reactions that bring about excitability in them. An increase in this factor could either hasten the development of excitability in the pace-setting neurons (i.e., those that had previously been most excitable) and thus shorten the interval between breaths, or it could facilitate the development of excitability in neurons that did not previously respond to the excitation wave; among these are the neurons which innervate the accessory inspiratory muscles, and when these come into play there will be an increase in the depth of breathing without any change in the rate. Actual observation (see page 540) indicates that although both of these things happen during hyperpnea, the *depth* of breathing usually increases before the *rate;* as a rule the rate is accelerated only when the expiratory muscles begin to contract vigorously in their phase, and this is seen only after the accessory inspiratory muscles have also become very active during inspiration. It would seem therefore that an increase in the chemical stimulus has more marked effects on those neurons that are inactive during quiet breathing than on those that are active. This could mean either that the excitation wave in the reticular formation has become stronger than before, and thus is able to reach neurons previously untouched by it, or that the neurons connected with the accessory inspiratory and expiratory muscles have become more excitable by reason of an increase in the number of CO_2 molecules within them. At present there is no compelling evidence upon which to choose between these conceptions, and the point has theoretical rather than practical importance.

The inspiratory act can thus be brought about entirely as the result of chemical factors operating in the center, and unless a certain number of carbon

dioxide molecules are present in the neurons of the center the rhythmic discharge of impulses ceases and apnea ensues (see Chapter XLIV). But as soon as inspiration begins, afferent impulses inhibitory to it also begin to reach the medulla from two sources, viz., the inhibito-inspiratory Hering-Breuer stretch receptors, and the pneumotaxic center in the pons. The former are activated by stretching of the alveoli, the latter by conduction of part of the inspiratory discharge from the reticular neurons upward to be relayed down again as an inhibito-inspiratory (= excito-expiratory) influence. The wave of inhibito-inspiratory impulses so aroused increases proportionately with the depth of inspiration, but since these inhibitory impulses can follow but never precede the inspiratory discharge and since the neurons and fibers of the center are nerve tissue and therefore subject to the all-or-none law (page 46), the strength of their discharge, once it has begun, cannot be diminished by such impulses and none of the inspiratory neurons that are going to respond will be kept by them from doing so. Thus these reflexes can terminate inspiration abruptly and prevent after-discharge or rapid reexcitation, but they cannot keep the depth of breathing from increasing as the chemical stimulus rises. *Depth of respiration therefore depends directly on the strength of the chemical stimulus and the sensitivity of the neurons to it.*

Inspiration comes to an abrupt close for three reasons: first, because the movement of fresh air into the alveoli reduces the CO_2 tension therein and thus decreases the chemical stimulus to the center; second, because the inspiratory neurons, once they have discharged impulses, are relatively inexcitable for a time, even if the chemical stimulus is not reduced, and since they acted in unison they also become inexcitable in unison; third, because the wave of inhibito-inspiratory impulses referred to above reaches its peak at the end of inspiration and therefore becomes stronger as the forces impelling inspiration become weaker. These inhibito-inspiratory impulses may act (as Adrian has suggested) by curtailing the discharge from the inspiratory neurons, thus shortening their phase of activity, bringing on their resting period more quickly and making it more complete, or (as Pitts believes) by increasing synaptic resistance in the reticular formation, thereby preventing repetitive discharge in closed circuits. In either case the end result is to permit the neurons to have a period of rest and recuperation after they have discharged impulses.* According to either conception, an inhibito-inspiratory discharge persisting throughout the respiratory cycle (as in rapid shallow breathing with the chest near the inspiratory position) would be harmful to the center, either because of interference with recovery processes by inhibitory impulses reaching the neurons during their resting phase (Adrian), or because a stronger motor discharge would be necessary to overcome increased synaptic resistance and the amount of energy required to prepare the neurons for this would be greater than would be the case otherwise (Pitts).

When inspiration ceases the neurons connected with the *expiratory* muscles are immediately released from the inhibitory influence exerted upon them by

*It is possible that adequacy of the inhibito-inspiratory reflex factor is largely or wholly responsible for the satisfaction that attends the inspiratory act during quiet normal breathing. The significance of this suggestion will be more evident when we come to consider dyspnea (page 648). At this time it may be well to point out that lack of satisfaction of the urge to breathe, even by the deepest inspiratory effort, constitutes the major difference between dyspnea (in which the act of breathing obtrudes unpleasantly upon the consciousness) and eupnea, or quiet breathing (in which it does not). Effective inhibition of the activity of the inspiratory neurons at the end of each inspiratory effort could certainly account for the latter and lack of it for the former, but the reader should understand that this is only a suggestion.

impulses from the inspiratory neurons (page 557). During quiet breathing the expiratory neurons apparently are not excitable enough, or are not sufficiently affected by the excito-expiratory impulses in the reticular formation, to produce an effective contraction of the expiratory muscles when this occurs, and the lungs simply empty gently by reason of the elastic recoil of the thoracic structures (muscles, ligaments, lungs) and the force of atmospheric pressure exerted upon the chest. This peaceful situation can be altered (as usual in respiration) either by nervous or chemical influences. Assuming that carbon dioxide is the specific chemical agent for the expiratory as well as inspiratory neurons, we may conclude that an increase in the tension of this gas in the blood causes an increase in the number of molecules of CO_2 in the expiratory neurons and therefore an increase in the intracellular reactions that make these cells excitable: when their excitability becomes sufficiently great a discharge of impulses to the expiratory muscles will occur whenever the inspiratory discharge ceases, and expiration then becomes an active process. Among the nervous influences that directly affect the expiratory neurons, special place must be given to those aroused by irritation of the expiratory passages (cough); these constitute a protective device that functions not only in the conscious subject, but in the anesthetized as well. It is probably for this reason that breathing remains vigorous under ether anesthesia although the response of the center to chemical factors is greatly depressed and chemoreceptor reflexes are less effective than under any other type of anesthesia; active expiratory efforts aroused by the irritant effects of the ether vapor replace these other mechanisms under such circumstances, and the relative safety of ether as an anesthetic indicates the adequacy of the replacement. Active contractions of the expiratory muscles, no matter how they are induced, are likely to lead to collapse of the alveoli sufficient to stimulate the expiratory Hering-Breuer receptors and give rise to a burst of excito-inspiratory impulses. This accounts for the fact that the rate of breathing is accelerated in dyspnea, for active contractions of expiratory muscles are a characteristic feature of dyspnea, and the expiratory phase of breathing is definitely shortened when the act is accomplished by vigorous muscular movements. In this way an increase in the chemical stimulus will increase the rate of breathing as well as its depth. Under pathological circumstances this excito-inspiratory discharge is not limited to the stage of deflation of the lungs but is persistent throughout the cycle; if this influence is sufficiently strong (i.e., if enough of the corresponding receptors are involved) the urge to breathe will persist throughout the respiratory cycle (since inspiration does not abolish it) and dyspnea ensues (page 648).

This brings us to a general consideration of excitatory nervous influences that are not in phase with the respiratory act, which includes all those items

TABLE XXI

RESPIRATORY RESPONSES TO EXERCISE*

	O_2 UPTAKE L./MIN.	PULMONARY VENT. L./MIN.	ARTERIAL pCO_2	ARTERIAL pH
At rest	0.25	5	39.8	7.41
Exercise	2.25	42	38.5	7.39
Exercise	3.0	62	37.0	7.43
Exercise	3.25	78	34.0	7.44
Exercise	3.6	118	29.0	—

*These data are derived from Fig. 27 of the paper by Nielsen.[118]

that are classified as "changes in excitability of the center to its normal stimulus" until something is learned about how this (which is obviously the result of something else) is brought about.

As an illustration of the magnitude of this factor Table XXI shows the results of an experiment by Nielsen[118] on a trained subject during exercise (on a stationary bicycle) of increasing intensity. From this and from many similar experiments, by Nielsen and by others, we can safely conclude that the respiratory adjustment to muscular exercise (which is certainly the commonest and probably the most important of all respiratory adjustments) can be secured without any increase, or with an actual decrease, in the carbon dioxide tension and hydrion concentration of the arterial blood. The only other identifiable chemical stimulus which could be held accountable for such a hyperpnea is oxygen-lack, but this cannot be the explanation here, first because the hyperpnea of exercise is much stronger than any that can be produced by carbon dioxide inhalation[119] whereas that of anoxemia is much weaker (page 565), and second, because actual studies of the arterial blood during moderate exercise (see Table XX, page 594) have shown no appreciable anoxemia. It is true that during very intense exercise some anoxemia may be present in spite of the most violent hyperpnea, but this occurs only at oxygen uptakes higher than 4 liters per minute.[120*]

If the extent to which pulmonary ventilation can be altered is any criterion of importance, the question now confronting us is by far the most important one in respiratory physiology. We have already seen (page 565) that the pulmonary ventilation elicited by muscular exercise is much stronger than the maximum obtainable by carbon dioxide inhalation. Barcroft and Margaria[18] found that the magnitude of the two hyperpneas is approximately in the ratio of 2:1; yet the subjects were much more uncomfortable (dyspneic) while breathing air enriched by CO_2 than during the hyperpnea of exercise, even though the latter was double the magnitude of the former. In Nielsen's experiments[119] the maximum pulmonary ventilation obtainable with CO_2 inhalation (50-60 liters per minute) was also about double that observed in the same subjects while exercising (110-120 liters per minute[118]). Yet the stronger hyperpnea of exercise may occur with no increase, or with an actual decrease, in any identifiable chemical stimulus in the blood (Table XXI). In some cases there may be an increase in one stimulus, such as the increased acidity (decrease of pH 0.074) of arterial blood noted in Table XX during exercise, and it is possible that the increase in respiration was due to this factor. It must, however, be remembered that an acid shift greater than this (pH 0.08) may produce only a slight (0.3 liter per minute) increase in respiration, or none at all, when it is brought about by the ingestion of ammonium chloride by resting subjects (page 560). It is much more probable that something other than any of the known chemical factors dominates respiratory control during exercise and that this factor is capable of stimulating respiration so markedly that the increased need for pulmonary ventilation consequent on the increased metabolic activity is completely satisfied. Until recently this factor could not be identified except

*It is inconceivable that results such as those depicted in Table XXI could have been due to accumulation of acid within the respiratory neurons, for these subjects were in a "steady state" at each level of exercise, and if equilibrium between the neurons and the arterial blood was not present here the permeability of the membranes to the stimuli must be so poor as to preclude any possibility that the respiratory center can serve a useful purpose in regulating the neutrality of the body (page 641).

by its result, which is to make the center more sensitive to the chemical stimulus;[118] this is exactly the same conclusion that was applied for many years to the hyperpnea of anoxemia. Just as the latter is now known to be due to the inauguration or augmentation of excitatory reflexes from the chemoreceptors (page 587), so the hyperpnea of muscular exercise, according to evidence submitted by Harrison and his collaborators,[70] is also due to excitatory reflexes aroused in the contracting muscles.

These investigators, like others who have studied this problem before and since, found that the hyperpnea of muscular exercise in man could not be explained by any demonstrable chemical change in the arterial blood. They also found that breathing was promptly stimulated by muscular movements of the hand even though the circulation was cut off by means of an inflatable bandage; this indicated strongly that a chemical product of muscular activity was not responsible, but it was still possible for some such product to enter the general circulation by way of the circulation in the bones. To eliminate this possibility they turned to experiments on anesthetized dogs, in which breathing was found to be stimulated when one hind leg was moved passively, even though the femur was severed, the femoral vessels clamped, and the leg connected with the body only by the sciatic nerve; when the nerve was cut, movements of the leg had no effect on breathing whether the femoral vessels were closed or open. These experiments show, not only that the factor responsible for the observed hyperpnea was not a chemical one acting on the center, but also that it was brought into action by movement of the affected limb; its absence after section of the nerve identifies it as a reflex; the fact that breathing was stimulated when the leg was moved passively indicates that irradiation of impulses from the higher motor centers into the medullary reticular formation was not responsible. Alam and Smirk[6] have recently made analogous observations (on man) with regard to the increase in blood pressure and pulse rate associated with exercise and have come to the same conclusion, i.e., that these physiological adjustments are also brought about by reflexes aroused in the exercising limb, though the reflexes they studied were probably evoked by chemical factors and, therefore, were different from those described by Harrison.

The hyperpnea of muscular exercise differs from others of reflex origin in several important respects: (1) it is associated with an increased production of CO_2, and while pulmonary ventilation usually increases sufficiently to prevent any rise in the CO_2 tension of arterial blood, there is no significant reduction as there is in other reflex hyperpneas; this is probably one of the major reasons why the hyperpnea of exercise is more vigorous than any that can be elicited by other reflex factors; (2) it may be associated with an increase in body temperature, which is another possible factor contributing to the vigor of the response; (3) it usually means voluntary mobilization of large masses of muscles, and while irradiation of impulses from the motor cortex into the reticular formation has been shown by Harrison[70] not to be entirely responsible, this cannot be ruled out as a contributing factor. According to Nielsen and Hansen,[120] the limiting factor in muscular exercise is the circulation, not the respiration; when muscular activity is carried to the limit of tolerance the available supply of oxygen carried by the blood is insufficient to meet the needs of the muscles and as a result of the "oxygen debt" thus contracted fixed acids

accumulate in the muscles and in the blood. The latter may then become acid enough to stimulate the chemoreceptors, thus bringing into play another factor that contributes to the hyperpnea; the same can be said of the arterial anoxemia that may result from very strenuous exercise.

The reflexes from the chemoreceptors of the carotid and aortic bodies may be regarded as the prototype of an excitatory nerve influence operating throughout the respiratory cycle. These reflexes have been studied sufficiently to establish the following characteristics of the hyperpnea so produced: When the stimulus is maximal, there is an increase in both rate and depth of breathing, but ordinarily only depth is increased; the hyperpnea is usually not so intense as that produced by CO_2 inhalation, but this may be only because the CO_2 tension of the blood is reduced by such a reflex hyperpnea and the excitability of the center is thereby diminished. The excitatory nerve impulses simply replace the chemical stimulus as the dominant factor in respiratory control. Just how this is done is unknown, but the proximity of the respiratory center to the nuclei of the glossopharyngeal and vagus nerves, for which the impulses carried from the carotid and aortic bodies apparently are destined, suggests that a set of strong excitatory impulses reaching this region might be able to create a disturbance in the adjacent reticular formation. As a matter of fact, impulses from the chemoreceptors can (in reactive animals) spread out so as to involve not only the medullary centers (respiratory, vasomotor, vomiting), but also motor nuclei, and violent generalized convulsions may ensue; these cease instantly when the chemoreceptor stimulation is terminated (Schmidt[138]—experiments on decerebrated cats).

Thus we emerge with a picture of the balance of direct chemical and nervous control of breathing that is very different from that which was almost universally held until recently. The adjustment of pulmonary ventilation to meet the changing requirements of the body for a supply of oxygen and the removal of carbon dioxide, under ordinary physiological conditions such as muscular exercise and the commonest emergencies such as anoxemia and acidosis, is brought about, not by a change in the chemical stimulus, but by the intervention of a new neurogenic factor which, in the case of anoxemia (and perhaps acidosis also), can be identified with certainty as afferent excitatory impulses from the chemoreceptors of the carotid and aortic bodies, but which, in the case of muscular exercise, can be characterized only by its result, which is to replace the chemical stimulus or—as it is commonly expressed—to increase the excitability of the center to that stimulus. There is no doubt that breathing can be stimulated by an increase in the chemical stimulus (carbon dioxide) in the blood when such increase is brought about intentionally in the laboratory, but there are no ordinary physiological emergencies under which this occurs and the response of the center to inhalations of carbon dioxide may therefore be a laboratory curiosity. The role of the chemical stimulus now appears to be to keep the central neurons in a state of optimum excitability with respect to neurogenic factors; until recently the general belief was that the relation is exactly the reverse of this, the neurogenic factors serving to keep the center properly oriented with respect to the chemical stimulus. Changes in the chemical composition of the arterial blood, as encountered under most physiological and many pathological conditions, are now to be regarded as results rather than causes of changes in pulmonary ventilation.

THE PART PLAYED BY CEREBRAL VASCULAR CHANGES IN RESPIRATORY CONTROL

Since it is probable that some peculiar respiratory phenomena owe their origin to changes in the tone of the blood vessels supplying part or all of the brain, before proceeding with a consideration of respiratory control under abnormal conditions we will do well to consider the possible relation of the cerebral circulation to the regulation of breathing. We have already seen (page 579) that the respiration of an anesthetized animal may, under favorable conditions, be shown to be subject to modification by altering the blood supply of the brain, and have indicated that such modifications of breathing are probably due to corresponding changes in the extent to which stimulant products of the metabolism of the cells of the center are permitted to accumulate there. It is to be hoped that the reader did not fail to note the statement (page 579) that changes such as this have little or no clinical importance. That, however, is not the case with the changes in the cerebral circulation that can be produced, presumably in the finer vessels, by experimentally induced changes in the chemical composition of the blood and (by inference) by certain disease conditions. This is a subject about which nothing was known until recently and although our knowledge is still far from complete it is now possible to draw at least a tentative picture of the factors involved.

The intrinsic control of the blood vessels supplying various parts of the brain can be shown to be brought into play either by changes in the carbon dioxide tension in the arterial blood, an increase in tension producing an increase in blood flow, a decrease, a diminution in flow (changes which involve the entire central nervous system), or by an increase in the local metabolism associated with increased functional activity, as evidenced by an increase in blood flow in the visual cortex when light is flashed into the eye (Fig. 241). Since this particular result was obtained in a part of the brain in which (so far as is known) there is no effective vasomotor nerve control, it is most probably due to the direct effect of the increased local CO_2 production resulting from the illumination. This necessitates the further conclusion that the effect must have been exerted upon capillaries rather than arteries, since only the former are permeable enough for the caliber of the vessels to be directly affected by changes in the CO_2 tension in the tissue surrounding them. In most other parts of the body the normal intrinsic control is accomplished mainly if not entirely by changes in tone of the muscle of the arterioles under the influence of impulses carried from the vasomotor center, and when these impulses are lacking the vessels dilate. In the brain, although vasomotor nerves are known to be present and can be shown by artificial stimuli to be capable of eliciting definite effects in some parts of the organ, these effects are different in important respects from those produced by corresponding vasomotor nerve stimulation in other regions of the body and are probably not to be regarded as evidence in favor of a normal vasomotor nerve control of cerebral blood vessels. This conclusion is borne out by the failure of cerebral blood flow to increase when the cervical sympathetic nerves are cut although flow in extracranial parts of the cephalic circulation (temporal or mylohyoid muscle, tongue) increases markedly (Schmidt and Hendrix,[144]). The intrinsic regulation of the circulation in the brain seems to differ from that elsewhere in the body in these important respects: in the brain the vessels possess a high intrinsic tone and their normal control depends on the extent to which they are kept from going into a state of excessive constriction (spasm) by chemical vasodilator agents, particularly carbon dioxide. In most other tissues the regulation depends on the extent to which tone is conferred by vasomotor nerve impulses upon vessels otherwise devoid of it; the vasodilator action of carbon dioxide on cerebral vessels probably is exerted upon the finest, most permeable ones (capillaries) while elsewhere the vasomotor control is necessarily strongest where smooth muscle is best developed (arteries, arterioles). This organization is well suited to the maintenance of constancy in the chemical state within brain cells in the face of changes in their own metabolic activity and in the chemical composition of the blood, which would not be the case if the

cerebral vessels were markedly influenced by vasomotor nerve impulses. In the coronary circulation the general arrangement appears to be very similar to that in the brain (page 506). Since the brain and the heart are the most susceptible of all body tissues to derangement by lack of oxygen, this organization was probably developed by a process of natural selection in which, among countless varieties of animals possessing innumerable types of vasomotor control, only those individuals whose cerebral and coronary arteries were not constricted by vasomotor nerve impulses survived emergencies such as violent exertion, emotions, struggle, flight, submersion, etc., to bear progeny that were similarly organized. *The brain and the heart apparently are too precious to the organism to be subjected to the caprices of the vasomotor center.*

Fig. 241.—Effect of illuminating eye on blood flow in visual cortex.

Cat—pentobarbital anesthesia, curare, artificial respiration. *Upper record*, blood flow in mesial surface of occipital lobe (registered by a small, cooled thermocouple inserted directly into the tissue). *Next record*—femoral blood pressure. Time tracing shows 5-second intervals. Between signal marks light from a small flashlight was flashed into opposite eye (previously protected from light). (From Schmidt and Hendrix: Proc. A. Research Nerv. & Ment. Dis. **18**: 229, 1938.)

Applying these deductions from experimental observations to the regulation of respiration, we may suppose that changes in tone of the finer vessels supplying the central neurons help to keep constant the number of molecules of carbon dioxide within them and thus to minimize the response of the respiratory center to changes in the chemical composition of the blood. The importance of this factor in the control of breathing under normal circumstances is problematical, but under certain abnormal conditions it can become very important. Perhaps the simplest of these is voluntary hyperpnea, by which—if it were sufficiently intense—one might expect the CO_2 tension of the blood to be so markedly reduced that the cells of the center would be completely inactivated for a dangerously long time. What is likely actually to happen when a vigorous subject makes an attempt to produce a maximal reduction in his arterial CO_2 in this way is the onset of complete unconsciousness within a few minutes, and with it the will to breathe is also lost, so that apnea ensues. After a brief interval (a minute or less) consciousness gradually returns and breathing is resumed, weakly at first, then more and more strongly until the full hyperpnea is again evident. This gives way once more to loss of consciousness and apnea. In this way a vigorous normal subject can produce perfectly typical Cheyne-Stokes respiration (page 656) in himself. These phenomena are not dependent upon a fall in blood pressure, for pressure may be unchanged or it may rise slightly, but it does not fall significantly. They are not due to fatigue, for they do not occur if alveolar air or 5 per cent CO_2 in air is breathed instead of room air: in such cases consciousness remains unclouded, the hyperpnea persists without interruption, and no periodicity appears. They are not due simply to the direct influence of the altered chemical composition of the blood upon the respiratory center, for if a vasodilator drug such as nitroglycerin is given beforehand, the result is the same as though CO_2 had been added to the inspired air (i.e., no periodicity), although the chemical changes produced in the blood by the hyperpnea would not be modified by this drug. Since nitroglycerin is one of the most effective of cerebral vasodilators,[144] we are justified in attempting to explain the above observations in terms of changes in the finer cerebral vessels consequent upon the voluntary hyperpnea. The course of events is probably as follows: as the CO_2 tension of the arterial blood is reduced by the hyperpnea the cerebral vessels constrict progressively until the cortical cells that are most susceptible to anoxia (those concerned with consciousness—see page 655) become incapacitated and consciousness is lost. Since the dominant factor in respiratory control—the will to breathe maximally—had come from these cells, and since the chemical stimulus to the respiratory center was greatly reduced by the voluntary hyperpnea, breathing diminishes progressively as consciousness is lost and it soon ceases entirely. During this period of apnea the subject is completely unconscious, does not respond to various stimuli—even to pain—and cannot be made to breathe. Meanwhile CO_2 accumulates, the cortical vessels begin to dilate, consciousness returns, and breathing begins again. During this phase the subject is perfectly conscious and will stop the hyperpnea instantly when requested to do so, but if that is not done another cycle of unconsciousness and apnea ensues, and so on.

In such cases there seems little doubt that the primary factor is periodic cessation of volitional hyperpnea consequent upon periodic unconsciousness, this

resulting from constriction of cortical vessels produced by reduction in the CO_2 tension of the arterial blood. Cyclical constriction of the blood vessels supplying only the respiratory center need not be called upon to explain the Cheyne-Stokes breathing thus produced. As encountered clinically, however, periodic breathing can frequently be made regular by cerebral vasodilator drugs (theophylline, or choline derivatives, page 658). Since there is no reason here to suspect that impulses from cortical cells are essential to the maintenance of breathing, it is most likely that the fundamental factor in such cases is an increased tone (spasm) of the vessels in the entire brain, including the respiratory center, that periodic relaxation of these by accumulation of CO_2 during the apneic period causes return of breathing and improvement of consciousness (in most cases), and that prolonged dilatation of the vessels by drugs causes return of continuous breathing and improvement in consciousness because a preexisting anoxic depression due to spasm of these vessels is now relieved. Why there should be a tendency toward spasm of cerebral vessels in such cases (or indeed the fact of its occurrence) remains to be determined. The coincidence of loss of consciousness, fall in blood pressure, and apnea which usually exists in Cheyne-Stokes breathing in man (page 657) suggests that the neurons of the cortex, the vasomotor center, and the respiratory center are all depressed simultaneously as a result of the spasm.

If it is true that constriction of cerebral vessels sufficiently intense to cause anoxia within brain cells can be produced by reduction in the CO_2 tension in the blood, it follows that cerebral anoxia is likely to be produced by any reflex hyperpnea. Since one of the most important causes of reflex hyperpnea is anoxemia, it follows that here (as in any physiological manifestation of anoxia) a vicious circle is set up; the hyperpnea causes reduction in the CO_2 tension of the arterial blood and since (as far as is now known) the influence of CO_2 on the cerebral vessels is stronger than that of anoxemia, they then constrict, thus adding to the anoxia already imposed upon the brain by the reduction in blood oxygen tension that induced the hyperpnea. At the same time the chemical stimulus to the respiratory center is decreased by reason of reduction in the CO_2 tension of the blood; this helps to diminish the hyperpnea and thus to weaken the most effective compensation for reduction in the oxygen tension in the inspired air (see Chapter XLV). If we add to this the possibility that chemoreceptor reflexes may have widespread stimulant effects on the central nervous system (page 606), it becomes probable that sudden relief of an anoxemia of considerable duration may have unexpectedly bad effects, such as unconsciousness, fall in blood pressure, and—if the neurons had been severely damaged by anoxia—respiratory failure and death. The latter may be responsible for an occasional fatal result from tracheotomy (page 664). Perhaps certain airplane crashes that have been blamed on plane failure were actually due to pilot failure brought about in this way, for it is known[115] that the beginning or resumption of oxygen inhalation at a high altitude sometimes causes unconsciousness and fall in blood pressure; this probably means that the reflex stimulus set up by anoxemia had been the dominant factor in maintaining the activity of the entire neuraxis, and when this is suddenly removed severe depression (perhaps contributed to by spasm of cerebral blood vessels) promptly ensues.[141]

Under abnormal conditions such as shock, hemorrhage, anoxemia, and (of special importance) anesthesia, the cerebral vessels dilate and their ability to respond to various influences is weakened or lost. The degree of this effect varies among different narcotics, being perhaps greatest with ether, but as far as is known it is elicited to some extent by all narcotics and in proportion to the severity of the poisoning. This may be viewed as a compensatory process, intended to increase the available oxygen supply to the brain cells when their ability to utilize oxygen is interfered with by the narcotic. But if it is true (as we have assumed above) that the tone of the finer cerebral vessels is normally altered in an attempt to maintain constant the chemical composition (particularly CO_2 tension) of the respiratory neurons, this adjustment must be interfered with by narcosis and the chemical stimulus to these cells should then be subject to greater fluctuations than would normally be the case. That this is true can be shown quite clearly in the case of the vasomotor center: in normal, unanesthetized human subjects who overbreathe voluntarily blood pressure does not fall, presumably because the chemical stimulus to the vasomotor neurons is kept, by constriction of the blood vessels supplying them, from falling dangerously, but in anesthetized men[147] a relatively small grade of overventilation causes quite marked fall in blood pressure, indicating that this protective mechanism is no longer effective.

CORRELATION OF THE GENERAL CIRCULATORY AND THE RESPIRATORY RESPONSES

As a rule the most powerful influences that affect the respiratory center affect the vasomotor and cardioaccelerator centers at the same time and in the same direction. If we accept Kapper's[90] conception of the reasons for the existence of a reticular formation (page 553) and take the viewpoint that the medullary reticular formation is organized around impulses carried from the viscera by the glossopharyngeal and vagus nerves, for the purpose of coordinating the muscular movements involved in the respiratory gas exchange with the environment, we can expect that various cells scattered in this region are connected to the respiratory muscles, the blood vessels, and the heart, thus constituting parts of the corresponding centers but with little or no special localization. That the wave of excitation sweeping over this region at inspiration involves the vasomotor and cardioaccelerator neurons is shown by the tendency of the impulses carried by the corresponding nerves to be grouped (like those to the respiratory muscles) in bursts synchronous with inspiration (Bronk). Applying to this organization the general conception that we have already applied to the adjustment of the respiratory movements to meet changing requirements (page 554), we can conclude that the number of cells discharging impulses over vasomotor and cardioaccelerator nerves will increase with the strength of the stimuli, nervous and chemical, and that these stimuli are in the main identical with those concerned in the control of respiration.

We may then conclude that the various neurons of the reticular formation, by responding to changes in the strength of the chemical stimulus brought to them by the blood or produced by their own metabolism, and to changes in the

balance among excitatory and inhibitory nerve impulses that constantly play upon them, can bring about changes in pulmonary ventilation and in blood flow through the brain that will produce an opposing change in the chemical state within these cells and thus restore to them the balance of affairs most to their liking. In so doing the chemical composition of the arterial blood and the circulation through tissues under vasomotor nerve control are modified to suit the desires of these cells in the medulla. Thus we can understand why the circulation and the respiration are both stimulated by an increase in the CO_2 tension in the blood, though here the rise in blood pressure produced by increased vasomotor activity may be more or less effectively opposed by the vasodilator action of CO_2 (page 475) and the hypertension therefore is not as conspicuous as the hyperpnea. We can also understand why afferent impulses from the carotid and aortic chemoreceptors stimulate the respiratory, vasomotor, and cardioaccelerator centers simultaneously, as shown by the hyperpnea, hypertension, and tachycardia elicited by acute anoxemia (page 676).

From this point of view special interest must be attached to the observations of Alam and Smirk[6] who found that a very considerable rise in blood pressure and acceleration of the heart rate occurred in normal human subjects when they were made to contract voluntarily a group of muscles (leg, forearm, even a little finger) whose blood supply was intentionally restricted. Since these effects did not ensue in the absence of circulatory restriction, they were not due to purely emotional or psychic factors, and they were not necessarily associated with pain. The authors interpret their observations as indicative of a reflex influence, aroused in muscles by accumulation there of metabolic products, and capable of producing powerful stimulant effects on the vasomotor and cardioaccelerator centers.

This conception has obvious and direct applications to the physiology of muscular exercise. According to recent evidence[10] the increased circulation required by an exercising muscle, secured mainly by an increase in the capillary bed therein, is not brought about until the exercise has continued for some time. Meanwhile the oxygen supply of the muscles is relatively inadequate and acid products of incomplete oxidation (such as lactic acid) appear in the blood stream, indicating considerable accumulation of such materials in the exercising muscles; the situation would then be essentially similar to that in the experiments of Alam and Smirk. When the circulatory readjustments in the exercising muscles become effective, the lactic acid of the blood diminishes toward or to normal even though the exercise is continued[10] and the "oxygen debt" contracted in the earlier stages is paid off; the subject now is in a "steady state" and the exercise entails less discomfort than before. This explains the well-recognized benefits derived from "warming up" before indulging in strenuous exercise.

The work of Harrison and his associates[70] indicates that reflexes similar to those described by Alam and Smirk affect the respiratory neurons in the same direction and at the same time as the vasomotor and cardioaccelerator system. We have just seen (page 604) that the hyperpnea of exercise can now, with some confidence, be attributed to a set of afferent impulses aroused in suitable receptors in the exercising muscles; these might be excited by changes in length or by products of the muscle's own metabolism. In the latter event the well-known phenomenon of "second wind" might be attributed to the onset of a

"steady state" by reason of vascular readjustments capable of meeting the increased demands of the muscles for oxygen, thus reducing the intensity of this reflex drive on the respiratory neurons; perhaps accumulation of lactic acid in the blood in the earlier stages and its disappearance subsequently (because of the same vascular phenomena in the muscles) acts through the carotid and aortic chemoreceptors as an additional factor in the same direction.

The reader should clearly understand that any such relation of the respiratory phenomena associated with muscular exercise to reflexes aroused in the muscles by metabolic products is at present entirely speculative. Further investigation seems very desirable.

CHAPTER XLII

THE GAS EXCHANGE IN THE LUNGS

The respiratory movements are the mechanical devices which enable the body to call upon the external environment (air) for a supply of oxygen and for the removal of CO_2. We have considered the nature of the respiratory movements and their regulation. The next step in the respiratory process is the gas exchange in the lungs, and we shall now inquire into the factors concerned in the uptake of oxygen by, and the removal of CO_2 from, the venous blood in its passage through the lungs.

The average normal adult consumes about 250 ml. of oxygen and produces about 200 ml. of CO_2 per minute when at rest. Any increase in activity increases the metabolism proportionately, and during strenuous exercise the above figures may be increased as much as twenty fold. All the oxygen consumed and all the CO_2 produced must pass through the membranes which separate the blood from the air in the lungs, and the process must occur very rapidly because the blood traverses the pulmonary circulation in one second or less. The interchange of gases takes place between the alveolar air and the venous blood which reaches the pulmonary capillaries from the right ventricle; the blood takes up oxygen and gives off CO_2, emerging from the lungs to enter the left auricle as arterial blood. The oxygen and CO_2 content of the atmospheric air, alveolar air, and blood in milliliters per 100 are approximately as follows (at sea level, and in a normal adult at rest):

	ATMOSPHERE	ALVEOLAR AIR	VENOUS BLOOD	ARTERIAL BLOOD
Oxygen	20.90	14.0	15	20
CO_2	0.03	5.6	52	48

During exercise the venous blood may contain as little as 5 ml. of oxygen and as much as 65 ml. of CO_2 per 100, but the arterial blood still emerges with practically the same amounts of these gases as it does when the subject is at rest. The rate of movement of air in and out of the lungs is increased during exercise, and this carries more fresh air into contact with the alveoli. But at the same time the rate at which the blood flows through the pulmonary capillaries may be increased as much as fivefold; if there were not an ample margin of safety in the provisions of nature for transferring the gases between air and blood the arterial blood would approach the venous in gas content during exercise and the result would be the same as that of strangling or drowning. It has been estimated that this margin of safety is about 100 per cent, meaning that half of the normal pulmonary surface is sufficient for the resting needs of the body.*

The transfer of the gases between the blood and the alveolar air is accomplished by diffusion, which means passage of the gas molecules from a place at which the pressure (tension) of the gas is higher to one at which it is lower.

*Graham (Surgery 8: 239, 1940) has recently reported survival of a young man after removal of four of the six pulmonary lobes; he believes that one-eighth of the total pulmonary tissue would suffice for the needs of the body under resting conditions.

The tensions of the gases involved in the respiratory exchange, in millimeters of mercury and in a normal resting adult at sea level, are as follows:

	INSPIRED AIR	ALVEOLAR AIR	VENOUS BLOOD	ARTERIAL BLOOD
Oxygen	159.00	100	40	90
CO_2	0.23	40	46	40

Before we proceed further with a consideration of the pulmonary gas exchange, we may profitably review those physical properties of gases which are concerned in the respiratory gas exchange.

THE GAS LAWS

The behavior of the respiratory gases in the lungs and tissues can be explained on the ground that gases are composed of discrete particles (molecules) constantly in motion in straight lines and with great velocity (kinetic hypothesis). According to this view the pressure or tension of the gas is due to the bombardment of the walls of the vessel which contains it by the constantly moving molecules. Anything that increases the bombardment must therefore increase the tension. The following gas laws express the factors of greatest physiological importance:

1. *For all gases, an equal number of molecules in the same space and at the same temperature will exert the same pressure* (*Avogadro's hypothesis*). It is evident that for two gases whose molecules are of different weight equal numbers of molecules will be obtained by measuring the gases in quantities proportional to their molecular weights. The molecular weight of any gas (referred to $O_2 = 32$) in grams (called a gram-molecule, or, for the sake of brevity, a mol) will occupy, at a temperature of 0° C. and a pressure of 760 mm., a volume of 22.4 liters. A pressure of 760 mm. (one atmosphere) means a pressure of 1033.3 grams per square centimeter, or about 15 pounds per square inch.

2. *As a gas is compressed its pressure increases in exactly the same proportion as its volume diminishes* (*Boyle's Law*). Thus a mol of any gas, when compressed at 0° C. to a volume of one liter, will exert a pressure of 22.4 atmospheres. The molecules now have to move a much shorter distance before they strike the walls of the containing vessel and the pressure is increased accordingly.

3. *Any gas expands when heated and contracts when cooled;* taking the volume at 0° C. as the standard, the gas increases in volume by $\frac{1}{273}$ for every degree C. rise in temperature. This means that if the volume is kept constant the pressure of a given gas is proportional to the temperature (*Law of Gay-Lussac*). Increased temperature increases the speed at which the molecules move, hence the rise in pressure.

One of the most characteristic properties of gases is their ability to diffuse, i.e., to pass from a point of higher pressure to one of lower and to expand and fill the entire available space. According to the kinetic hypothesis, diffusion is the result of the continuous movement of the gas molecules, and since the pressure is believed to afford a measure of that movement, the rate of diffusion is directly proportional to the pressure (Boyle's Law) and temperature (Law of Gay-Lussac); it is inversely proportional to the square root of the density (molecular weight) of the gas (Graham's Law).

When gases are taken up by liquids (as they must be to participate in the gas exchange in the body) the same laws continue to operate, but the situation is modified by the ability of the liquid to absorb or to combine chemically with each gas. This determines the volume of the gases that can be taken up by the liquid at a given temperature and pressure. The volumes (in milliliters per 100) of oxygen, CO_2, and nitrogen that can be dissolved by water, blood plasma, and whole blood, when exposed at 38° C. to an atmosphere of each gas (760 mm. pressure) are as follows:

	WATER	PLASMA	BLOOD
Oxygen	2.37	2.3	2.3
CO_2	55.5	54.1	54.1
Nitrogen	1.2	1.2	1.1

The corresponding volumes dissolved by the blood at the pressures existing in the alveolar air and at 38° C. are approximately:

Oxygen	0.3 ml. per 100 (volumes per cent)
CO_2	3.0 ml. per 100
Nitrogen	0.8 ml. per 100

These are the volumes of the gases taken up by the blood in purely physical solution; the amounts taken up in chemical combination are not included. The latter are much greater than this (see page 627) except for nitrogen, which does not combine chemically with the blood, does not participate in the gas exchange, and is carried entirely in physical solution. The important point is that CO_2 is by far the most soluble of the respired gases, and this is probably responsible for much of the ease with which CO_2 diffuses in the body.

4. *The law of solution of gases in liquids* (*Henry's Law*) states that the weight (i.e., the number of molecules) of a gas absorbed by a given liquid with which it does not combine chemically is directly proportional to the pressure of the gas, other things being equal.

5. *The law of partial pressures of gases dissolved in liquids* has to do with the pressure exerted by individual members of a mixture of gases. If the gases do not react chemically with one another (and none of the respiratory gases do) the partial pressure or tension of each constituent of the mixture is that which it would exert if no other gas were present. The tension of each gas in the liquid is the same as its partial pressure in the gaseous phase; the molecules of each gas move into the liquid until the pressure is equal in the two phases and are kept from leaving the liquid by the pressure existing in the gaseous phase. If the pressure in the latter is increased, more gas molecules pass into the liquid until the pressure in the two phases becomes equal at the higher level, and if it is decreased, gas molecules escape from the liquid until the pressure in the two phases is again equalized at a lower level. *The tension of a gas in a liquid can be regarded as the force with which the gas molecules are constantly striving to escape.* The tensions of the respiratory gases in the blood are due entirely to that portion of each gas which is dissolved in the plasma; the larger amounts carried in chemical combination serve as reservoirs from which additional gas molecules are liberated to pass into the plasma when the tension of the gas is reduced, or in which additional molecules are stored when the tension is increased. Gases in chemical combination do not exert a tension and therefore cannot diffuse.

The tension of a gas is of the utmost importance as regards its physiological effects, for this is the measure of the force which drives its molecules through living membranes and which determines the number of molecules of the gas that will enter and leave the body. The oxygen which enters the body must diffuse from the atmospheric air into the alveolar air, from the alveolar air into the blood, and from the blood into the tissues; the CO_2 which is exhaled must follow the same pathways in the reverse direction. The physical factors which govern the rates of diffusion at each step are: (1) the difference in tension, (2) the solubility of the gas in the blood, (3) the temperature, and (4) the density of the gas. Solubility, temperature and density are constant in a given individual under given conditions, so that the rate of diffusion of gases into and out of the body depends directly and solely upon the tensions of the gases. But to enter or leave the blood and the tissues the gases must traverse living membranes which interpose barriers to the free diffusion of gas molecules. Furthermore, we have so far taken into account only the rate at which the gases diffuse and have said nothing about the size of the surface available for the process in the lungs, though this is obviously a factor of utmost importance in determining the total amount of gas that can enter and leave the body at a given difference in tension between venous blood and alveolar air. The membranes and surfaces involved are those of the lungs and we shall now consider the part played by the tissues of the lungs in the pulmonary gas exchange.

THE PART PLAYED BY THE LUNG IN THE GAS EXCHANGE

Until recent times it was assumed that the lungs behave like passive sacs and that the parts having the thinnest walls—i.e., the alveoli—are the ones which expand and contract as the volume of the thoracic cavity alternately increases and decreases. Observations made by means of the x-rays and the bronchoscope have shown that this is by no means the case. They indicate that the ventilation of the lung involves active changes in that organ and that most of the changes in capacity of the lung with respiration take place in the air passages and not in the

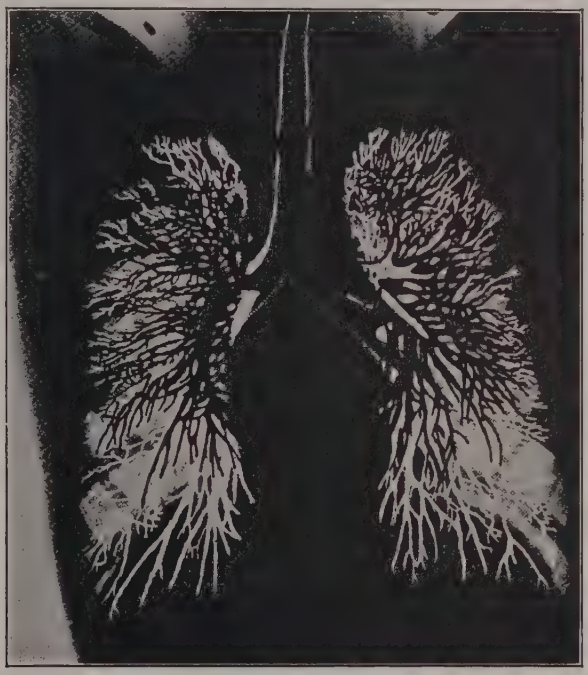

Fig. 242.—Changes in bronchi during the respiratory cycle. X-ray photographs of human lungs superimposed and retouched; expiratory phase in black, inspiratory in white. (From Macklin: Am. J. Anat. 35: 303, 1925.)

alveoli. In order to understand the part played by the lung itself in external respiration, it is necessary to refer to the structure of the organ (see page 547).

The *unit* of the lung is a respiratory bronchiole with the alveolar ducts and alveoli arising from it, together with the corresponding blood vessels, lymphatics, nerves and connective tissue (Maximow[112]). This is the distensible or "bellows" part (Keith), as well as the respiratory part of the structure. These units are found throughout the entire thickness of the lung, as well as on surfaces, such as the mediastinal and posteromedial, and the posterior aspects of the apices, where they cannot be directly expanded by the inspiratory movements of the

thorax. It follows therefore that the alveoli would be very unevenly and unequally ventilated unless there were some special provision for moving air into and out of them. Recent studies have shown that the alveoli are actually ventilated, not by expansion of their walls, but by elongation and expansion of the air passages from which they arise. The alveoli themselves are said to change very little in size during the respiratory cycle; although the lung enlarges in all directions during inspiration and contains a correspondingly increased volume of air, most of the change is in the air passages, and principally in the finest ones—the infundibula of Keith[92] or the alveolar ducts of Macklin.[109]

Changes in the length of the larger air passages can readily be demonstrated roentgenologically (Fig. 242). With inspiration the entire system elongates, the trachea and bronchi move downward, and the root of the lung moves downward and forward. Although the finer passages cannot be visualized so clearly, it is most probable that they too elongate. As a consequence the lung opens up like a concertina, with the difference that the lung comes broader and thicker as well as longer (Macklin[109]). The deeper the inspiration, the greater is the elongation of the bronchial tree. With inspiration the air passages become not only longer but also wider. This can be seen in the larger passages with the bronchoscope, and the finer ducts, including the orifices from which the air enters the alveolar sacs and alveoli, doubtless behave similarly. The elongation is due to the outward pull exerted by the movement of the thoracic walls away from the lung surfaces; the widening of the passages as they elongate is doubtless due in part to the same cause, but it is probable that the smooth muscle in their walls undergoes a decrease in tone during inspiration (Macklin). With expiration the entire bronchial tree shortens in all directions and the tubes become narrower at the same time. The shortening can be accounted for by recoil of elastic tissue stretched during inspiration; the narrowing implies a return of tone to the smooth muscle of the air passages.

Ventilation of the alveoli appears to be accomplished, not by expanding them as passive sacs and thus sucking in air from the alveolar ducts, but by a lengthening and expansion of the ducts and an increase in the size of the openings into the alveolar sacs (Macklin). Air rushes toward the alveoli during inspiration because the pressure in the air passages is now lower than atmospheric, because the resistance to the onward flow of air is lessened by reason of expansion of the ducts, and because the capacity of the duct system is increased by simultaneous elongation and widening. All these factors vary directly with the depth of breathing. If it is true that the alveoli themselves do not expand the incoming air can be drawn only as far as the alveolar ducts, but the currents set up in the passages by the inflowing stream of air, aided by the inspiratory enlargement of the openings into the air sacs, make possible a free interchange of gases between the ducts and the alveoli. In fact, air currents in the bronchi are capable of sustaining an adequate alveolar ventilation in the absence of all respiratory movements, as Meltzer[116] showed. He found that if a constant current of air or oxygen is supplied under gentle pressure through a catheter inserted in the trachea to the region of its bifurcation an animal can be kept alive for long periods without breathing. This procedure, known as intratracheal insufflation, has come into practical use in operations on the lung or other thoracic contents, and to some extent for purposes of resuscitation.

The *bronchial musculature* plays a part in alveolar ventilation by relaxing with inspiration and regaining its tone with expiration, thus enlarging the air passages as they elongate. Existing evidence indicates that this muscle system is under the control of two sets of nerves, the vagus which is motor, and the sympathetic which is inhibitory. The changes in tone associated with breathing are probably brought about through these nerves, but whether both are concerned or only one, and if the latter, which one, is not known. Anatomical studies indicate that the muscle envelops the openings of the air sacs into the alveolar ducts in a sphincter-like structure, relaxation of which during inspiration would greatly facilitate the ventilation of the alveoli (Macklin[109]). The muscle is most highly developed in the region of the bronchioles, and this is where the movement of air is most likely to be interfered with by excessive tone of the muscle fibers. Such a condition produces *asthma*, which occurs in a variety of diseases, conspicuously in those associated with sensitization to foreign proteins. A number of drugs and poisons may produce bronchial spasm, notably those which are parasympathomimetic (vagomimetic), such as muscarine, choline derivatives, eserine, and pilocarpine, and those which excite smooth muscle irrespective of its innervation, such as morphine and its congeners, and histamine. Bronchial constriction also occurs in anaphylaxis, and Dale[44] suggests that it may actually be due to liberation of histamine from tissues damaged by exposure to the protein to which they are sensitized. Spasm of bronchial muscle is relaxed by sympathomimetic drugs, such as adrenalin and ephedrine; that due to vagomimetic agents is also relaxed by atropine. Asthma is not always due to spasm of bronchial muscle; congestion in the pulmonary circulation, as in cardiac disease, may produce it, probably by pressure on the finer air passages by engorged blood vessels, and chronic inflammatory processes may also impinge on the finer tubes. A number

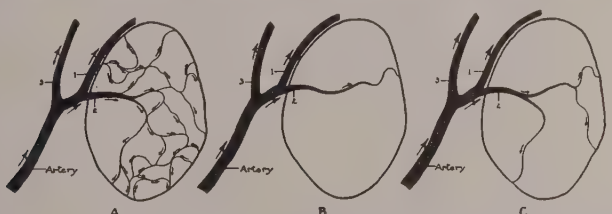

Fig. 243.—Changes in circulation in the wall of an air sac of a cat's lung. Intratracheal insufflation—no respiratory movements. *A*, *B*, and *C* are spontaneous changes: length of capillary channels in *A* is about 3.6 times that in *C* and 9.2 times that in *B*. (From Wearn et al.: Am. J. Physiol. **109**: 236, 1934.)

of observations have been made which indicate that the bronchial musculature is capable of wavelike, peristaltic movements adapted to the extrusion of mucus and foreign material; the factors responsible for such movements are unknown. Perhaps the rhythmic changes in tone of the smooth muscle of the respiratory passages are another manifestation of the organization of the medullary reticular formation and of the dominance of the excitation wave which traverses it at each inspiration; since bursts of impulses having the rhythm of respiration can be found in the vasomotor and cardiac nerves, it is certainly possible that the same rhythm might also extend to this other autonomic innervation. Relaxation of this musculature with the first breath (i.e., with the first excitation wave in the reticular formation) may be necessary to secure inflation of the lungs after birth (see page 674).

The alveolar surfaces of the lungs are well suited to permit free diffusion of gases between blood and air. The two media are separated only by the endothelium of the capillaries and the epithelium of the alveolar walls, there being only a very tenuous supporting framework and, as we have already seen (page 547), there is even some doubt as to the existence of the epithelial layer in the alveolar walls; the barrier to diffusion is about the smallest possible. The surfaces are enormous. Willson[163] has calculated from careful measurements made on a piece of human lung that both lungs, in the position of full inspiration, would have a total air-bearing surface of about 70 square meters. This includes both

nonrespiratory (air passage) and respiratory (alveolar) surfaces, and since there is no means of determining anatomically the relative proportions of the two, he concludes that the alveolar area available for the exchange of gases must be something less than 70 square meters. Gertz[56] estimates the total respiratory area at about 50 square meters while Krogh[95] gives the figure of 90 square meters. The total area of the capillaries in the alveolar walls of the human lungs is stated by Maximow[112] to be 140 square meters. This figure was doubtless obtained by measurement of the vascular area in fully injected dead tissue and must be taken to represent the maximum vascular surface that could be available for the diffusion of gases. The recent studies of Wearn and his co-workers[162] show that the circulation in the alveolar capillaries of the cat is highly variable from moment to moment in the same animal. Capillaries may open and close (Fig. 243), depending upon a regulating mechanism on the arterial side. Excep-

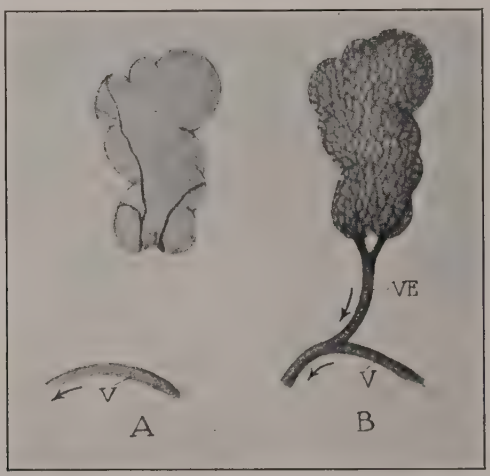

Fig. 244.—Spontaneous opening of entire capillary bed in an air sac of a cat's lung. *A*, only a few capillaries open; *B*, entire capillary bed carrying blood—circulation now failing. *V*, branch of pulmonary vein; *VE*, venule which became visible only as capillaries opened. tionally the entire vascular network opens and passes blood (Fig. 244) but the circumstances under which this occurs have not yet been determined; CO_2 excess and oxygen-lack apparently do not have this effect. The part played by this variability in the alveolar circulation in the physiology of respiration is at present unknown. We must at least conclude that of the maximum area (140 square meters) of alveolar capillaries, only a fraction—and probably a small though variable one—is ordinarily utilized in the respiratory act. Even so, the surfaces available for the exchange of gases are enormous.

THE RATE OF DIFFUSION OF THE RESPIRATORY GASES THROUGH THE MEMBRANES OF THE LUNGS

The *diffusion constant* is defined by M. Krogh[96] as *the total number of milliliters of the gas which pass through the entire pulmonary membrane per*

minute for each millimeter difference in tension on the two sides of the membrane (alveolar air and blood). For oxygen the values in normal adult males were found to vary from 23 to 43 during rest and from 37 to 56 during work; in females the corresponding values were somewhat lower (from 22 to 29). Bøje[25] subsequently obtained nearly identical results. Much of the increased rate of diffusion during exercise is attributed to increase in the rate of blood flow through the lungs.* Harrop[71] found diffusion constants for oxygen ranging from 25 to 45 in eight healthy men who were members of Barcroft's expedition to the Andes in Peru (see page 689). The diffusion constant for CO_2 is about 20 to 30 times as great as that for oxygen (A. Krogh[94]), which is another manifestation of the ease with which CO_2 can pass through living membranes.

We have seen (page 614) that the tension of oxygen in the alveolar air is 100 mm. while that in the venous blood is 40 mm. when the subject is at rest, and may be considerably lower when he is exercising. The difference in tension of oxygen on the two sides of the membrane is therefore 60 mm. when the subject is at rest and higher when his oxygen consumption increases. Even with a diffusion constant of 23, enough oxygen could diffuse into the blood to furnish $23 \times 60 = 1380$ ml. of oxygen per minute, and with the same difference in tension (60 mm.) but the higher diffusion constant (56) during exercise, 3360 ml. of oxygen could diffuse per minute. The largest oxygen consumptions recorded in man lie between 4,000 and 5,000 ml. per minute, and these are unusually high. Under such circumstances the venous blood would certainly have a lower oxygen tension than 40 mm., and the difference in tension of oxygen between alveolar air and blood would therefore be greater than 60 mm. The oxygen tension of alveolar air would probably also be greater than 100 mm. because of the increased depth of respiration, and this would increase further the head of pressure which drives oxygen through the alveolar membrane. Bøje[25] calculated that the greatest amount of oxygen that can be taken up in the lungs from ordinary air is 4,500 ml. per minute. Nielsen and Hansen,[120] in experiments in which trained athletes were subjected to exercise (on a stationary bicycle) to the limit of their capacities, found that the maximum possible oxygen absorption from room air was about 4,200 ml. per minute, which was not enough to meet the metabolic needs of the body. When oxygen was added to the inspired air, so as to raise the oxygen content to 45-47 per cent, the amount of oxygen absorbed increased by 500-800 ml. per minute, breathing was easier, and the subjects were able to continue the maximum effort longer than before. This indicates that it is possible to produce oxygen-lack in a normal individual by increasing the call for oxygen to a level higher than 4 liters per minute (approximately), but this can happen only in individuals in perfect physical condition. The elimination of carbon dioxide, however, remains adequate under all normal conditions, no matter how vigorous the exercise (until the circulation fails). Although the difference in tension of this gas is only 6 mm. (venous blood 46 mm., alveolar air 40 mm.) in the resting subject, the fact that CO_2 can traverse the alveolar membranes 20 to 30 times as readily as oxygen more than compensates for the smaller difference in tension, and CO_2 leaves the blood in the lungs even more readily than oxygen enters it. Even in disease, retention of CO_2 seldom if ever occurs without much greater shortage of oxygen.

*The work of Wearn and his co-workers is suggestive in this connection, for an increase in the area of the capillaries in which venous blood is exposed to alveolar air in the lungs would certainly work in this direction. There is as yet no evidence that this occurs during exercise.

We must not forget, however, that the blood is exposed to the alveolar air only for one second or less. This time is insufficient for complete equilibrium to be established between the oxygen tension of the alveolar air and that of the blood leaving the lungs. The oxygen tension of arterial blood is actually 5 to 25 mm. lower than that of the alveolar air; 90 mm. may be regarded as the average normal oxygen tension in arterial blood. This is the most vulnerable point in the entire process of respiration, for it is obvious that if the oxygen equilibrium between alveolar air and arterial blood is incomplete even when the rate of blood flow through the lungs is basal and the surfaces available for diffusion are normal in character and extent, there is likely to be a much greater disparity when cardiac output is increased, or the diffusion surface is reduced by disease. Dill,[47] Nielsen and Hansen,[120] and Krogh,[95] for various reasons, believe that this disparity is not due to a diffusion gradient (i.e., to inability of the membranes to pass sufficient amounts of oxygen into the blood) but rather to relative slowness of dissolved oxygen at reaching equilibrium with hemoglobin. An increase in the oxygen tension in the alveolar air would increase both the number of oxygen molecules and the rate at which they diffuse through the layers of blood in the pulmonary vessels and thus increase the oxygen saturation of the blood; the amount of the gas in physical solution (and therefore immediately available for the gas exchange of the tissues (page 699) would also be increased in proportion to the increased tension. Carbon dioxide diffuses so much more readily that the tension of this gas in the arterial blood is the same (40 mm.) as that in the alveolar air under all circumstances.

Secretion of Oxygen by the Lungs.—Under all ordinary circumstances the oxygen tension of the arterial blood is a little lower than that of the alveolar air, but as long as the oxygen tension in the inspired air is not reduced, enough oxygen can diffuse into the blood to supply all of the needs of the body for that gas. When the pressure of oxygen is reduced, however, the situation is different. There now are fewer molecules of oxygen in a given volume of air and they diffuse less rapidly. Is it possible for the alveolar epithelium under such circumstances to secrete oxygen into the blood so that the pressure of oxygen in the arterial blood is higher than that in the alveolar air?

For many years it was believed by some physiologists (notably J. S. Haldane) that this is the case, and a number of carefully made experiments seemed to support the belief. The practical importance is considerable, for when a person has been exposed for some time to a low tension of oxygen, as at a high altitude or in certain diseases which interfere with the oxygenation of the blood, he becomes acclimatized and can carry on activities which were impossible for him before compensation occurred. We will refer to this subject again in Chapter XLV. Haldane believed that the symptoms of oxygen-lack are relieved largely because of secretion of oxygen into the blood. However, Barcroft's party found during their sojourn at 14,200 feet above sea level that blood drawn directly from an artery was darker in color than at sea level and was only about 85 per cent saturated with oxygen instead of the 95 per cent which is normal at sea level; the oxygen tension of the blood was no higher than that of the alveolar air. Natives who had never lived elsewhere and whose ancestors had probably lived at that altitude for eight hundred years also showed arterial oxygen saturations of 85 per cent or less. Talbot and Dill[156] have made similar observations in six natives who resided and worked at an altitude of 17,500 feet; the oxygen saturation of arterial blood, collected by direct arterial puncture, ranged from 67.6 to 84.6 per cent and averaged 75 per cent; in ten temporary residents at the same altitude and at the same time of year the average arterial oxygen saturation was 76.2 per cent. "The absence of any difference between the arterial saturation in the temporary and the permanent residents suggests that permanent acclimatization is not associated with any significant change in this function of the blood" (Talbot and Dill).

The evidence at present is overwhelmingly against secretion of oxygen into the blood by the human lungs under any conditions. The uptake of oxygen in the lungs probably depends entirely upon diffusion of the gas from a point of higher pressure to one of lower, and the tension of oxygen can probably never become higher in the arterial blood than in the alveolar air; it is generally lower in the blood than in the alveolar air.[95]

Variations in the Rate of Diffusion of Oxygen.—The rate at which oxygen diffuses into the blood varies considerably among different individuals who presumably have normal pulmonary membranes. This is probably due partly to differences in the area of the capillaries in which blood is exposed to the alveolar air, partly to differences in the thickness of the membranes, and partly to differences in the effectiveness of the alveolar ventilation. Harrop[71] found that those men of Barcroft's expedition who had a diffusion constant for oxygen greater than 40 had practically no symptoms of mountain sickness when living at an altitude of 14,200 feet while those with lower coefficients suffered more or less severely. During a stay of several weeks at the higher altitude their diffusion coefficients did not change appreciably. There is at present no evidence that the oxygen diffusion constant increases when acclimatization takes place. It is true that Harrop also estimated the coefficients in five American engineers who had lived for two years or more at high altitudes and found them all above 40: the lowest was 41.5 and the highest was over 65, the latter in a man who had been a prominent runner during his college days. This may mean that some improvement takes place after long exposure to low tensions of oxygen, but it may also mean that only men who have high coefficients to begin with can stand the strain of continued activity at high altitudes.

It is certain, however, that the oxygen diffusion coefficient can be decreased considerably by diseases which reduce the effective surfaces in the lungs (such as emphysema, pneumonia, or collapse of the lung) or which cover the alveolar walls with a layer of fluid (as the result of inhalation of irritant gases such as chlorine, or possibly in cardiac disease).

Determination of the Tensions of the Gases in the Blood.—The tension in the arterial blood can be determined by exposing the blood at body temperature to mixtures containing different tensions of oxygen and CO_2 until one is found which neither gains nor loses gas during the exposure; this must have the same gas tensions as the blood. Direct determinations of the gas tensions in the circulating arterial blood were made by Krogh by means of a special microtonometer connected directly with an artery. A small bubble of air is exposed to the circulating blood, so that after a time actual equilibrium of gas tension becomes established between the bubble and the gases of the blood. This apparatus is shown in Figs. 245 and 246. It consists of a graduated tube of narrow bore surrounded by a water jacket. To the upper end of the graduated tube a small syringe is attached. The lower end of the graduated tube expands into a thistle-shaped bulb, closed below by a cork, through which is inserted a tube (inflow tube) ending near the top of the bulb in a fine opening and connected outside with an artery. An outflow tube is also connected with the thistle-shaped bulb.

At the beginning of the experiment the thistle-shaped bulb and the graduated tube are filled with physiological saline. By means of the syringe a small bubble of air is then introduced, so that it lies at the junction of the thistle-shaped bulb and the graduated tube. As the blood is allowed to enter through the inflow tube, it is ejected in a fine stream around the bubble of air, which moves about in the stream. The blood displaces the saline out of the bulb into the side tube. After the bubble has been subjected to the influence of the blood for some minutes, the gases in it come into perfect equilibrium with those in the blood.

The percentage of O_2 and CO_2 in the bubble will therefore correspond to the tension of these gases in the blood. The analysis is effected by drawing the bubble into the graduated tube by means of the syringe, measuring its capacity, transferring it into a bulb containing KOH, which absorbs the CO_2, then taking it back into the capillary tube and again measuring. The shrinkage obviously corresponds to the amount of CO_2. The bubble is then transferred into potassium pyrogallate solution, where the O_2 is absorbed.

The same procedure can be used to determine the tensions of the gases in blood drawn directly from an artery of man: a small bubble of air is introduced into the blood in a tonometer like Krogh's and after equilibrium has been reached the gas tensions of the air in the bubble are determined by analysis.

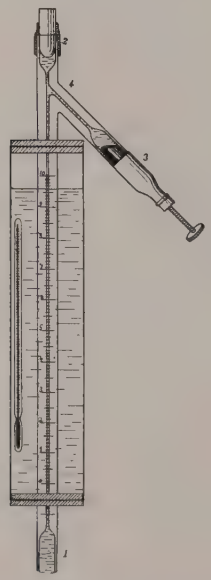

Fig. 245.

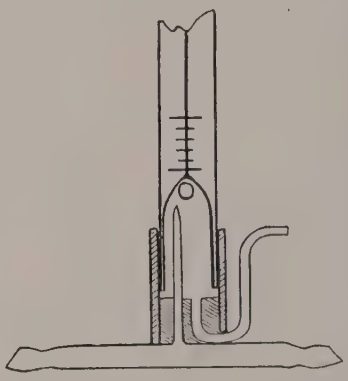

Fig. 246.

Fig. 245.—The gas analysis pipette for the microtonometer shown in Fig. 246. For description see text. (From A. Krogh: Skand. Arch. f. Physiol. 20: 259, 1907-08.)

Fig. 246.—Microtonometer, to be inserted into a blood vessel. The small circle represents the bubble of air. For further description see text. (From A. Krogh: Skand. Arch. f. Physiol. 23: 193, 1909-10.)

The tensions of the gases in the mixed venous blood can be determined directly in animals by withdrawing blood from the right ventricle, but this procedure obviously is not to be recommended for studies in man. Christiansen, Douglas, and Haldane[34] introduced a method which depends upon ascertaining the gas mixture which is in tension equilibrium with the venous blood, but in this case the lungs are used as the equilibrating vessel. The procedure in determining the CO_2 tension of the venous blood is as follows. Three Douglas bags provided with valves are used: *A* containing 7.5 per cent CO_2; *B*, 7 per cent, and *C*, 6.5 per cent. The subject expires as deeply as possible through a respiratory valve and then fills the lungs with air from bag *A* (by connecting the bag with the inspiration valve and taking three deep breaths). He then expires about half way through a piece of hose pipe, and a sample of air is collected in a Haldane gas sampling tube or all-glass syringe. The remaining half of the air is retained in the lungs for five or six seconds when it also is expired through the hose pipe, and another sample is collected. The two samples of alveolar air are analyzed for CO_2. Exactly the same procedure is repeated with the air in bags *B* and *C*. The alveolar venous tension of CO_2 will then correspond to the percentage in the bag with which no change occurred in the two alveolar samples. Thus,

supposing with bag *A* that Sample 1 contained 7.4 per cent CO_2 and Sample 2, 7.2 per cent, and with bag *B*, that both Samples 1 and 2 contained 7 per cent, and with bag *C*, that Sample 1 contained 6.6 per cent and Sample 2, 6.8 per cent; then clearly equilibrium was established at 7 per cent CO_2 which is, therefore, the venous tension.

In Pearce's method[125] the person first of all inspires from a gas meter containing a gaseous mixture with about 10 per cent of CO_2. Immediately after filling the lungs, he makes a rapid forced expiration into a tube provided with a valve having four openings. This valve is turned through a complete circuit during the expiration, so that four fractions of the expired air can be collected in rubber bags connected with side tubes opening opposite each of the four openings in the valve. The first fraction will contain a little less than 10 per cent CO_2, the second distinctly less, while the third and fourth should contain the same percentage, indicating that equilibrium between the CO_2 of the alveolar air and the blood has been attained. This figure gives us the tension of CO_2 in the venous blood of the lungs. In Henderson's method the rebreathing is performed into gas receivers containing 6 per cent CO_2.

The tension of O_2 in the venous blood of the lungs (mixed venous blood) may be determined by the application of similar principles. After a deep expiration nitrogen is inspired for 3-5 breaths (10-20 sec.) from a rubber bag provided with valves, and a sample of alveolar air is immediately taken. The percentage of O_2 in this alveolar air will be found to be the same whether it be taken after 3 or 5 breaths, showing that an equilibrium with the tension of this gas in the blood must have been reached. If taken earlier, the O_2 will be too high, and if taken later it will be too low, because the blood will have circulated twice round the body (Barcroft). This oxygen percentage is somewhat lower than that corresponding to the tension of oxygen in the venous blood of the lungs, on account of the fact that the tension of CO_2 in the alveolar air, under the conditions of the experiment, corresponds to that of the arterial blood.

THE PART PLAYED BY CHEMICAL CHANGES IN THE BLOOD IN THE LUNGS

In addition to the factors which we have just been considering, the uptake of oxygen by the venous blood is aided to a considerable extent by the removal of CO_2 from it. On the other hand, the removal of CO_2 is aided to an even greater extent by the uptake of oxygen. This brings us to a consideration of the physicochemical changes in the blood associated with the transport of the respiratory gases—a question which will be taken up in the next chapter. At this point it will suffice to summarize briefly the changes which assist in bringing about the gas exchange in the lungs.

The oxygen and CO_2 carried by the blood (with the exception of the 0.3 ml. of O_2 and 3.0 ml. of CO_2 which are simply dissolved in each 100 ml. of the plasma) are held in chemical combinations which represent the equilibria of a series of reversible physicochemical reactions at the tensions of oxygen and CO_2 existing in the plasma. As soon as the tensions of the gases are altered, all of these chemical combinations are altered correspondingly. In the lungs the venous blood (oxygen tension 40 mm., CO_2 tension 46 mm.) is exposed to an oxygen tension of 100 mm. and a CO_2 tension of 40 mm. Oxygen promptly diffuses into the plasma and CO_2 out of it. The added oxygen is taken up by the hemoglobin, which is thus transformed from the reduced to the oxygenated form. Oxyhemoglobin is a stronger acid than reduced: it requires alkali, which it takes from other anions (Cl^-, HCO_3^-) present in the erythrocytes. As a result of this appropriation of a number of cations by oxyhemoglobin a corresponding number of chlorine ions diffuse out into the plasma and bicarbonate ions diffuse into the erythrocytes in exchange. This bicarbonate is promptly decomposed to CO_2 and water, the reaction being greatly accelerated by an enzyme (carbonic

anhydrase) present within the erythrocytes, and the CO_2 diffuses out into the plasma and thence into the alveolar air. The oxygenation of hemoglobin also leads to the splitting off of CO_2 from amino groups with which it was held in combination before the hemoglobin took up oxygen but which can no longer hold it when the molecule becomes more acid as a result of oxygenation; this CO_2 also diffuses out into the plasma and thence into the alveoli. Meanwhile as soon as the CO_2 dissolved in the plasma can diffuse out of the blood into the alveolar air the CO_2 tension of the plasma falls, the equilibria of the reactions concerned in binding CO_2 are disturbed, and CO_2 is liberated from chemical combination for that reason as well as the ones mentioned above. The loss of CO_2 from the blood makes it more alkaline and this enables hemoglobin to combine with more oxygen than it would if the reaction of the blood remained the same. Thus the uptake of oxygen turns CO_2 out of the blood and the loss of CO_2 enables the blood to take up more oxygen. As we shall see, this relation is exactly reversed in the tissues.

CHAPTER XLIII

THE TRANSPORT OF THE RESPIRATORY GASES BY THE BLOOD

We have now completed our survey of the various mechanisms involved in *external respiration;* i.e., in the exchange of gases between the blood and the external environment (air) in the lungs. We have seen how the respiratory movements are adjusted to the needs of the body for the uptake of oxygen and the removal of CO_2. We have considered the factors which cooperate to change the character of the blood from venous to arterial in its passage through the lungs, and in so doing have encountered some examples of the remarkable way in which the blood performs its share of the respiratory process. It is necessary now to consider the respiratory function of the blood, for this is the link which connects the gas exchange in the lungs with that in the tissues; tissue respiration will be taken up in Chapter XLVII.

Let us consider first the amounts of the gases in the blood. These are best determined by the method of Van Slyke and Neill.[143] The apparatus used is shown in Fig. 247.

At the start of an analysis the analyzer is filled with mercury. A measured quantity of blood is then drawn into it together with a gas-free reagent which combines with the blood so as to liberate its gases from chemical combination. The mixture is then subjected to a torricellian vacuum by lowering the mercury leveling bulb. After shaking for a few minutes the gases will be completely removed from the blood and will exert a pressure upon the surface of the mercury. This pressure is measured by determining the height of the mercury column in the vertical tube at the left that is required to bring the volume of the gases to a constant volume, e.g., 2 ml. Strong alkali (NaOH) is then introduced to absorb CO_2, and, after mixing, the gas pressure is again read; this reading is lower than the first, and the difference represents the CO_2. To determine the oxygen, sodium hyposulfite solution is introduced to absorb it and the oxygen pressure is determined by the extent to which absorption of the gas has reduced the pressure.

The reagent for determination of CO_2 alone contains lactic acid to decompose the alkali compounds of the blood and caprylic alcohol to prevent foaming. For determination of oxygen alone a mixture of potassium ferricyanide (which liberates oxygen from hemoglobin, while changing the latter to methemoglobin), saponin (which causes hemolysis—a necessary step since ferricyanide cannot enter the red cells) and caprylic alcohol is used; CO_2 is absorbed by NaOH before the first reading is made. To determine both CO_2 and oxygen in the same sample of blood a mixture of lactic acid, sodium ferricyanide, saponin, and caprylic alcohol is used; the CO_2 is first measured by absorption with NaOH and the oxygen is then estimated by absorption with sodium hyposulfite.

This manometric method permits greater precision than the original volumetric procedure of Van Slyke, although the apparatus used in the latter is simpler and the method is sufficiently accurate for most clinical work. For details the reader is referred to Peters and Van Slyke (vol. 2).

The average amounts of oxygen and CO_2 in the blood of healthy young adults at rest are approximately (in ml. per 100):

	Oxygen	CO_2
Mixed venous blood	15	52
Arterial blood	20	48

The amounts of these gases that can be dissolved (without chemical reaction) by blood at 38° C. under the tensions existing in the alveolar air are about 0.3 ml. of oxygen per 100 (at a tension of 100 mm. Hg) and about 3.0 ml. of CO_2 per 100 (at a tension of 40 mm. Hg). Now the amount of oxygen con-

sumed by an individual at rest is seldom if ever less than 200 ml. per minute. To supply this minimal quantity of oxygen to the tissues the cardiac output need be only 4 liters per minute when each 100 ml. of blood gives up 5 ml. of oxygen, as it normally does. But if the body had to depend upon the oxygen carried in simple solution in the blood, and even if the entire 0.3 ml. carried by each 100 ml. were taken out of it (which could scarcely occur) the heart would have to pump nearly 70 liters of blood per minute to meet the needs of the body at rest—an impossible task. During exercise the oxygen consumption often is greater than 3 liters per minute; to meet this demand from oxygen carried in solution in the blood would require a cardiac output of more than 1000 liters per minute. The importance of some agent for carrying oxygen in chemical combination is of course evident.

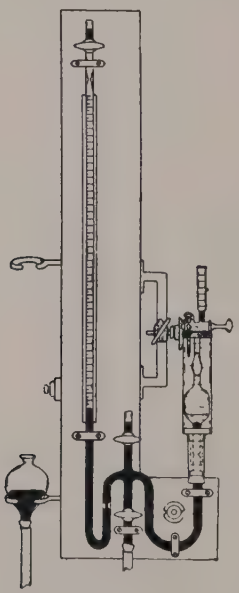

Fig. 247.—Manometric apparatus for blood-gas analysis. (From Van Slyke and Neill: J. Biol. Chem. 61: 523, 1924.)

It must not be supposed that the gases carried in physical solution are unimportant simply because their quantities are relatively small. On the contrary it is only the gases in solution that can take a direct part in the gas exchange; the larger amounts that are carried in chemical combinations are physiologically inactive until the gas molecules are released from chemical combination. But we have just seen that the amounts of oxygen carried in solution are entirely insufficient for the needs of the body, even at rest. The basic fact of respiration beyond the lungs is thus brought to our attention. It is this: *The volume of each of the respiratory gases carried in chemical combination in the blood varies directly with the tension of the same gas in the plasma and inversely with the tension of the other gas.*

The general scheme is as follows: If we start with the mixed venous blood of a resting individual we find a tension of oxygen of 40 mm. and a tension of CO_2 of 46 mm. After the blood leaves the tissue capillaries and until it arrives in the lungs there is no opportunity for gas to enter or leave it and the reversible chemical reactions in which the gases are involved come to an equilibrium at those tensions. In the lungs the blood is exposed over an enormously large surface and in a very thin layer to a higher tension of oxygen (100 mm.) and a lower tension of CO_2 (40 mm.). Oxygen immediately diffuses into the plasma and CO_2 out of it. This upsets the equilibria. More oxygen can be taken up in chemical combination at the higher tension and this promptly occurs; less CO_2 can be bound chemically at the lower tension and its combinations are accordingly broken down to liberate CO_2 molecules which diffuse out of the blood and into the alveolar air. At the same time, as we have already seen (page 625), the taking up of oxygen automatically reduces the ability of the blood to carry CO_2 and most of the elimination of CO_2 by the lungs is due to that fact. Loss of CO_2 also makes the blood less acid and enables it to combine with more oxygen.

The arterial blood as it leaves the lungs has gained 5 ml. of oxygen and has lost 4 ml. of CO_2 per 100 (page 627). The tension of oxygen is about 90 mm. and that of CO_2 40 mm. There can be no further change until the blood reaches the capillaries, and the chemical reactions involving the gases therefore come to an equilibrium at those tensions. In the tissues the processes which we have just described in the lungs are reversed. The tension of oxygen is low (15-27 mm. in the subcutaneous tissues of man at rest—Seevers[146]) and oxygen diffuses out of the plasma; this causes a breakdown of the chemical combination in which oxygen is held and more of the gas escapes into the plasma and thence into the tissues. The tension of CO_2 is high—over 46 mm.—and this gas diffuses into the blood which therefore becomes more acid. This leads to a reapportionment of alkali in the blood, one result of which is to decrease the amount of oxygen which can be held in chemical combination at that tension of oxygen; consequently more oxygen molecules are liberated into the plasma and thence into the tissues. After losing oxygen the blood is able to carry more CO_2 in chemical combination and thus a new equilibrium is attained—that of mixed venous blood, with which we started. The blood has lost 5 ml. of oxygen and gained 4 ml. of CO_2 per 100.

Such is the situation when the body is at rest. During violent exercise the amount of oxygen taken out of each 100 ml. of blood may increase from 4 ml. to 15 ml. or more, so that the blood which reaches the lungs may contain as little as 4 ml. of oxygen per 100. Yet it still emerges from the lungs containing 20 ml. of oxygen per 100. The adequacy of this mechanism to meet greatly changing conditions is thus quite evident.

The substance responsible for practically all of the transport of the respiratory gases is hemoglobin. Its properties and the reactions through which its functions are carried out will now be considered briefly.

THE PROPERTIES OF HEMOGLOBIN

A complete discussion of the chemical composition and known properties of hemoglobin is beyond the scope of this book. The reader is referred to Barcroft[13, 14] and Peters and Van Slyke[126] for such information. For our purposes it is sufficient to note the following essential facts.

In man and other mammals hemoglobin normally exists only inside the erythrocytes; consequently any molecule or ion that enters or leaves a chemical combination with hemoglobin must pass through the walls of these cells which are freely permeable to oxygen and CO_2 and to anions such as Cl^- and HCO_3^-, but not to cations such as Na^+ and K^+. Hemoglobin is a protein which has a molecular weight of about 68,000 and contains iron in the ferrous state, four atoms to each molecule of hemoglobin. It possesses a number of groups which are capable of combining with alkali and acid, and at the hydrion concentration encountered inside the erythrocyte (about pH 7.25) it acts as a weak polyvalent acid (a buffer) which has combined with alkali (mainly potassium) to form soluble salts. Hemoglobin comprises 32 per cent of the contents of the erythro-

cyte, the remainder consisting of water (65 per cent) and inorganic salts (3 per cent). The ability of hemoglobin to combine reversibly with oxygen depends entirely on the iron of the molecule. One atom of ferrous iron (Fe^{++}) combines with one molecule of oxygen (O_2). This is also true of the combination with carbon monoxide. When the hemoglobin iron is oxidized to the ferric form (Fe^{+++}) it loses its power to combine reversibly with O_2 or CO; this is methemoglobin, which cannot carry oxygen. The function of hemoglobin as a carrier of CO_2 depends partly upon the formation of unstable carbamino or carbamate compounds ($CO_2 + RNH_2 \rightleftharpoons RNHCOOH$), but in much larger part upon the buffer property, which in this case means that hemoglobin can give up alkali when CO_2 enters, thus forming bicarbonate, and take up the alkali again when the bicarbonate is broken down. About 20 per cent of the CO_2 that is given off in the lungs is carried in the blood in carbamino combination with hemoglobin while about 70 per cent is carried as bicarbonate; the alkali for the latter is obtained from the buffer groups of hemoglobin. The formation of bicarbonate takes place almost entirely within the erythrocytes because the first step in the process is hydration of CO_2 molecules to carbonic acid ($CO_2 + H_2O \rightleftharpoons H_2CO_3$); this reaction occurs much too slowly for physiological purposes unless it is catalyzed by the enzyme *carbonic anhydrase,* which is found only inside the erythrocytes. When carbonic acid is formed inside the erythrocyte, bicarbonate ions are at once split off and some of them (about one third) remain inside the erythrocytes, but the remainder diffuse out into the plasma. For this to occur an equal number of chlorine ions must diffuse into the cells from the plasma in exchange for the bicarbonate ions (Roughton).

The quantity of hemoglobin in the blood varies greatly with age. (See Peters and Van Slyke,[126] p. 544.) In healthy adult males between 16 and 60 years of age, it is about 15.6 grams per 100 ml. of blood. One gram of hemoglobin can combine (at full saturation) with about 1.34 ml. of oxygen. Consequently 100 ml. of blood from a normal adult male, when saturated with oxygen, should contain 20.9 ml. of oxygen in chemical combination. Since the oxygen content of blood can be determined very accurately, the oxygen-combining power is the easiest way to determine accurately the hemoglobin content of blood, and for adult males the standard is that just given, i.e., 20.9 ml. O_2 capacity per 100 ml. blood. In females the hemoglobin content is normally about 90 per cent of that of males and the corresponding standard is about 19 ml. O_2 capacity per 100 ml.*

THE COMBINATION OF HEMOGLOBIN WITH OXYGEN

"The physiological value of hemoglobin as an oxygen carrier lies in the fact that its affinity for oxygen is so nicely balanced that in the lungs hemoglobin becomes 95 to 96 per cent oxygenated, while in the tissues and capillaries it can give up as much of the gas as is demanded. If the affinity were much less, complete oxygenation in the lungs could not be approached: if it were greater, the tissues would have difficulty in removing from the blood the oxygen they need. Because the affinity is adjusted as it is, both oxyhemoglobin and

*These figures must not be confused with those for the oxygen content of arterial blood, which is normally 95 to 96 per cent saturated with oxygen; arterial blood of males should contain about 20 ml. of O_2 per 100 ml., that of females about 18 ml. per 100. It is a coincidence that atmospheric air at sea level contains 20.9 ml. of oxygen per 100 ml. of air—the same figure as that for the oxygen capacity of the blood of men.

reduced hemoglobin exist in all parts of the circulation, but in greatly varied proportions'' (Peters and Van Slyke[126]).

The ability of hemoglobin to function as an efficient carrier of oxygen depends upon the fact that the amount of oxygen held by it in chemical combination varies directly with the tension of oxygen and inversely with the tension of CO_2. As we have seen (page 629) venous blood takes up oxygen and loses CO_2 in the lungs, while in the tissues the process is reversed. Hemoglobin acts as a storehouse for oxygen, delivering to the tissues as much of the gas as they require. The need is expressed in the tensions of oxygen and CO_2 in the tissues: the more active the metabolism, the lower the tension of oxygen and the higher the tension of CO_2 to which the blood is exposed in the capillaries.

The combination of oxygen with hemoglobin is a reversible chemical reaction: $Hb + O_2 \rightleftharpoons HbO_2$. The relative amounts of reduced (Hb) and oxygenated (HbO_2) hemoglobin depend entirely upon the pressure (tension) of O_2 provided that everything else is unchanged. But increased acidity diminishes the amount of oxygen with which hemoglobin can combine at a given oxygen tension, and decreased acidity has the opposite effect. The tissues contain large amounts of

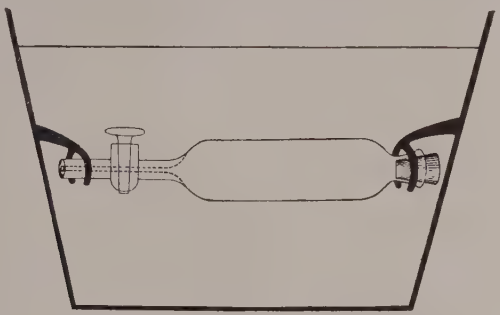

Fig. 248.—Barcroft's tonometer for determining the curve of absorption of oxygen by hemoglobin. (From Starling's Physiology.)

CO_2. This gas diffuses very readily into the blood and expels oxygen from it both directly, by combining with hemoglobin to form carbamates which reduce the oxygen-binding power of hemoglobin, and indirectly by combining with water to form carbonate, from which hydrogen ions are dissociated, thus increasing the acidity of the blood. Hence oxygen leaves the blood in the tissue capillaries both because the oxygen tension outside the capillaries is lower than that inside and because the ability of hemoglobin to combine with oxygen at the existing tension is reduced by diffusion of CO_2 and fixed acid (if present) into the blood. In the lungs both factors cooperate to oxygenate the hemoglobin: the oxygen tension is high and the CO_2 tension is low, so that acid diffuses out of the blood as oxygen diffuses into it.

These facts are conveniently demonstrated by plotting curves to show the extent to which hemoglobin is saturated with oxygen at different tensions of the gas. These are known as *dissociation curves.* To obtain the data necessary to construct them one must first expose small amounts (e.g., 3 ml.) of blood or hemoglobin solution to relatively large amounts (about 400 ml.) of gas mixtures in which the oxygen tension is known. This is done in glass vessels, known as tonometers (Fig. 248), which are slowly rotated in a water-bath at a known temperature until the blood, which is spread out in a thin film on the walls of the tonometers,

comes to equilibrium with the gas mixture. The tension of oxygen in the blood is now equal to that in the gas mixture, and the latter can be calculated from the percentage of oxygen which it contains. The oxygen content of each of the blood samples is then determined by a suitable method such as that of Van Slyke (p. 627). One now knows the amount of oxygen taken up by 1 ml. (or 100 ml.) of that particular blood or hemoglobin at each of the oxygen tensions that were investigated.

It must be realized that the amount of oxygen taken up by a sample of blood at a given tension of oxygen varies with the amount of hemoglobin present. To correct for this and to permit comparison between different samples of blood, it is necessary to know the quantity of oxygen which the blood can take up when fully saturated. This is determined by exposing the blood to an excess of room air (O_2 tension 159 mm. Hg at sea level) until no more oxygen is taken up. The oxygen content of this sample represents full saturation (HbO_2 = 100 per cent; Hb = O). At lower oxygen tensions there will be varying mixtures of reduced hemoglobin and oxyhemoglobin and the percentage saturation, $\frac{\text{oxygen content}}{\text{oxygen capacity}} \times 100$ is the figure used in plotting dissociation curves.

The effect of CO_2 on the dissociation curves for oxygen is studied by adding CO_2 in varying tensions to the gas mixtures in the tonometers. The effects of temperature, concentration of hemoglobin, and electrolyte content have also been investigated in a similar way.

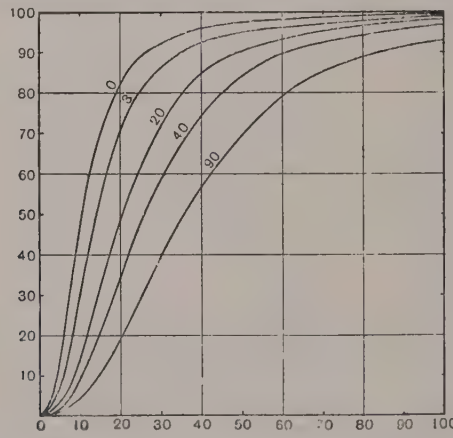

Fig. 249.—Dissociation curves of human blood exposed to 0, 3, 20, 40, and 90 mm. CO_2. Ordinate, percentage saturation. Abscissae, oxygen pressure. (From Joseph Barcroft.)

Dissociation curves obtained in this way are shown in Fig. 249. The tensions of oxygen are plotted as abscissae, the percentage saturation of the blood with oxygen as ordinates. All of these curves were obtained with the same sample of human blood at 38° C. The important points are these:

The oxygen dissociation curves of blood are characteristically S-shaped.* They are shifted to the right as the CO_2 tension is increased, which means that

*Pure solutions of hemoglobin at room temperature, if weak (1:500) and free from such electrolytes as are found in blood plasma, give a hyperbolic dissociation curve; i.e., the curve rises steeply in a straight line, then flattens out horizontally. Stronger solutions give an S-shaped curve and it is probable that the typical S-shaped curve of blood is to some extent due to the high concentration of hemoglobin. Either raising the temperature or adding electrolytes introduces a slight S-shape into the dissociation curve of a weak hemoglobin solution, and these factors also help to give the curve of whole blood its characteristic appearance, but they are relatively unimportant. For our purposes the behavior of whole blood at 38° C. is of greatest importance, and the only variables that need be considered are the tensions of oxygen and the tensions of CO_2 or the hydrion concentration; the hemoglobin concentrations and electrolyte content are constant. Temperature is probably higher in active tissues than elsewhere, and this shifts the curve to the right; i.e., it decreases the affinity of hemoglobin for oxygen at the existing tensions of oxygen and CO_2; this undoubtedly helps to unload oxygen in active tissues.

the addition of CO_2 (or increased acidity in general, for an equal change in pH produced by any other acid has the same effect) reduces the ability of hemoglobin to hold oxygen, and a loss of CO_2 (or greater alkalinity) enables hemoglobin to combine with more oxygen, at the same oxygen tension. Arterial blood (O_2 = 90 mm., CO_2 = 40 mm.) is about 95 per cent saturated with oxygen; i.e., it contains about 20 ml. of O_2 per 100 ml. Under resting conditions mixed venous blood (O_2 = 40 mm., CO_2 = 46 mm.) is about 72 per cent saturated with oxygen, i.e., it contains about 15 ml. of O_2 per 100; in the tissues the blood has lost 5 ml. of O_2 per 100. The curve obtained at 40 mm. tension of CO_2 is the one which most closely approximates ordinary physiological conditions; the steepest slope is seen to occur when the oxygen tension falls below 40 mm., which means that as the tissues need more oxygen the hemoglobin parts more and more readily with it and the blood emerges more and more nearly reduced. At a tissue oxygen tension of 30 mm., for instance, this blood would be only 55 per cent saturated; i.e., it would have yielded more than 9 ml. of O_2 per 100. At a tissue oxygen tension of 10 mm. it would be about 8 per cent saturated, i.e., it would emerge with less than 2 ml. of oxygen per 100 and would have given up more than 18 ml. per 100. Since a fall in tissue oxygen tension, if due to increased activity of the tissue, would also be accompanied by an increase in CO_2 tension and in temperature, the blood will yield oxygen at a higher tissue oxygen tension than it would if the CO_2 tension remained at 40 mm. and the temperature at 38° C.

TABLE XXII

EFFECT OF OXYGEN AND CARBON DIOXIDE TENSIONS ON OXYGENATION OF HEMOGLOBIN IN THE HUMAN BLOOD

O_2 TENSION	O_2 PHYSICALLY DISSOLVED	PROPORTION OF HEMOGLOBIN COMBINED WITH OXYGEN AT FOLLOWING CO_2 TENSIONS			
		CO_2 = 3 MM.	CO_2 = 20 MM.	CO_2 = 40 MM.	CO_2 = 80 MM.

(From Peters and Van Slyke: Quantitative Clinical Chemistry, Vol. I, Baltimore, 1931, Williams and Wilkins Co.)

Table XXII gives data which illustrate these points, and Fig. 250 is a chart in which the relation of the oxygen saturation of blood to the oxygen tension and acidity of the blood is shown under two sets of conditions—rest, and work strenuous enough to increase the oxygen consumption to seven times the resting value. The blood of this subject (Fig. 250) at rest was giving up 4.6 ml. of oxygen per 100 ml. in his tissues (arterial blood 96 per cent saturated with oxygen, venous blood 74 per cent saturated; oxygen capacity assumed to be 21 ml. per 100). At work his blood gave up just twice as much oxygen (9.2 ml. per 100), changing from 94 per cent (arterial) to 50 per cent (venous) saturation. The arterial oxygen tension was 78 mm. at rest, 73 mm. during exer-

cise. The venous oxygen tension was 41 mm. in the resting state, 32 mm. at work. If the acidity of the blood had not been increased in the tissues when work was done (i.e., if the pH of the venous blood had remained at 7.35, its arterial level) the blood would have emerged from the tissues 56 per cent oxygenated at 32 mm. oxygen tension instead of the 50 per cent actually observed, and each 100 ml. of blood would have yielded only 8 ml. of oxygen instead of 9.2 ml. In other words, lowering the pH of the plasma from 7.35 to 7.28 by diffusion of CO_2 (and possibly acids such as lactic) into the capillaries accounted for the liberation of about 13 per cent of the total amount of oxygen given up to the tissues, the remaining 87 per cent being set free because of the lower oxygen tension alone. Greater acidity would have a greater effect, and it would be

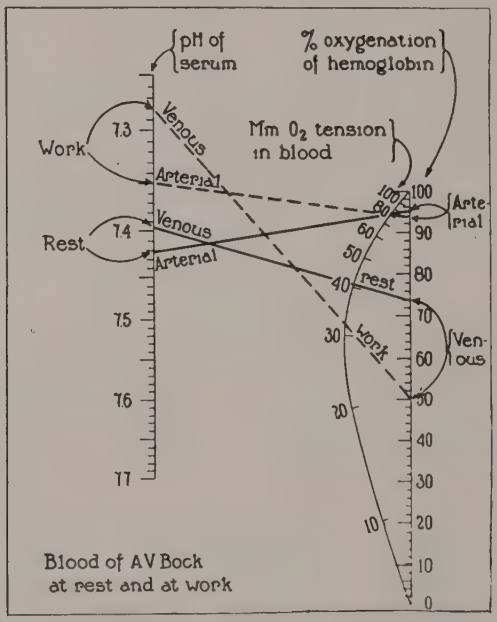

Fig. 250.—Line chart showing amounts of oxygen bound by hemoglobin of the blood of subject shown in Table XXII, at rest (unbroken lines) and while doing work sufficient to increase oxygen intake seven fold (broken lines). A straight line drawn through selected points on any two of the three scales cuts the third scale at the point corresponding with the other two. (From Peters and Van Slyke: Quantitative Clinical Chemistry, Vol. I, Baltimore, 1931, Williams and Wilkins Co.)

most marked when the tissues are most in need of oxygen, as at high altitudes, or during violent exertion, or in diseases in which anoxia occurs. In such circumstances lactic acid, in addition to CO_2, is likely to enter the blood from the tissues and the acidity of the blood would thereby be increased to an unusual degree; blood pH may fall below 7.0 if muscular exercise is carried to the point of collapse, as in a long run culminating in a sprint (Laug[98]).

From these examples we see why it is that the characteristic S-shaped dissociation curve of hemoglobin gives an excellent picture of the ability of this substance to yield oxygen in proportion to the needs of the tissues, for the steepest part of the curve lies just below the oxygen tensions usually found in

the tissues at rest and the CO_2 produced by the tissues helps to a slight but important extent in releasing oxygen from its combination with hemoglobin. We can also see why increased alkalinity of the blood will cause the hemoglobin to combine with more oxygen and to yield it only at a lower oxygen tension.

One important point has not yet been mentioned, namely, the significance of the flat top of the curve. If we follow the dissociation curve at 40 mm. CO_2 tension in Fig. 249 we see that an increase of oxygen tension from 0 to 30 mm. leads to 60 per cent saturation of the blood with oxygen; a further rise to 60 mm. oxygen tension causes the blood to be almost 90 per cent saturated; a further rise to 100 mm. oxygen tension only makes the saturation 96 per cent. The importance of this is quite evident if we consider what happens when the body is exposed to decreased oxygen tensions, as at high altitudes, for even though the oxygen tension falls to 60 mm. (corresponding to an altitude of 14,000 feet) the blood is still nearly 90 per cent saturated with oxygen. At oxygen tensions lower than this the saturation of hemoglobin begins to fall sharply, and it is largely for this reason that permanent residence above 14,000 feet is unpleasant or hazardous for most people.

The velocity of the reaction $Hb + O_2 \rightleftharpoons HbO_2$ has not been taken into consideration up to this point, for in obtaining data for dissociation curves one allows sufficient time for equilibrium to be attained. It is probable that a given molecule of hemoglobin traverses the pulmonary circulation in not more than one second, and the time spent in the tissue capillaries is about the same. Unless the reactions which we have just been describing can take place in the body within one second the dissociation curves have little practical importance. This feature of the problem has been attacked by Hartridge and Roughton[72] who observed with a special spectroscope the rate at which the absorption bands of reduced hemoglobin change to those of oxyhemoglobin when reduced blood is mixed with oxygenated Ringer's solution and made to flow through an observation chamber. They found that under their experimental conditions reduced hemoglobin becomes oxyhemoglobin in less than 0.01 second. Oxyhemoglobin was also found to give up its oxygen with extreme rapidity, and the reaction is accelerated by increased temperature or increased CO_2 tension. The one second allotted a molecule of hemoglobin to take up oxygen in the lungs and to yield it in the tissues is much more time than is required for the reaction $Hb + O_2 \rightleftharpoons HbO_2$ to proceed to completion in either direction. But we must remember that the gas diffuses through the capillary walls and through the membrane of the erythrocytes, as well as through the blood plasma, and this takes a certain amount of time. We have already seen (page 622) that the blood leaving the lungs has not quite come to equilibrium with the oxygen tension of the alveolar air (90 mm. or less in blood, 100 mm. in alveolar air). This is probably because of incomplete exposure of the hemoglobin molecules to the oxygen; equilibrium of the tension of this gas between the plasma in contact with the alveolar surfaces and the interior of the erythrocytes apparently is not reached during the time available for the process, so that the equilibrium actually struck is at a tension of oxygen lower than that in the alveolar air.

THE TRANSPORT OF CARBON DIOXIDE

The total amount of CO_2 that can be extracted from the arterial blood of normal persons averages about 48 ml. per 100, the normal range being from 41 to 55 ml. At rest the amount in venous blood is about 4 ml. more than this,

i.e., about 52 ml. per 100; during muscular activity the venous blood may contain as much as 65 ml. of CO_2 per 100, or even more, but in the passage through the lungs practically all of the excess CO_2 is lost and the arterial blood emerges with only a little more CO_2 than it holds under resting conditions. The CO_2 tension of arterial blood is about 40 mm. It is the same as that of the alveolar air, because CO_2 diffuses so rapidly that the blood and the alveolar air normally always come to complete equilibrium with respect to CO_2 tension. For the same reason the tension of CO_2 in the venous blood is probably equal to that in the tissues; at rest this tension is about 46 mm., while during exercise it may rise to 60 mm. The amount of CO_2 that can be dissolved by blood exposed to a tension of 40 mm. of CO_2 at body temperature is only about 3 ml. per 100. Consequently 45 of the 48 ml. of CO_2 yielded by 100 ml. of arterial blood must be in chemical combination. About one-fifth of it (about 10 ml.) is combined directly with amino groups of hemoglobin (carbamino-bound or carbamate CO_2, RNHCOOH). The remainder is carried as bicarbonate ($BHCO_3$), and practically all of it is formed inside the erythrocytes through the action of the enzyme carbonic anhydrase. After bicarbonate ions are formed inside the erythrocyte most of them (two-thirds or more) diffuse out of the cells into the plasma and an equal number of chlorine ions diffuse into the cells in exchange. Thus as the bicarbonate content of the plasma increases, the chloride content decreases, and conversely. The base (B) does not pass from cells to plasma, for the wall of the erythrocyte is impermeable to cations; anions can traverse it and the interchange of Cl^- with HCO_3^- accounts for the changes in bicarbonate content of the plasma.

The amount of CO_2 that can be carried by a given sample of blood varies directly with the CO_2 tension and inversely with the oxygen tension. This can be shown by constructing CO_2 dissociation curves.

To obtain the necessary data samples of blood are exposed at 38° C. in tonometers to varying tensions of CO_2 until equilibrium is attained. The CO_2 contents of the blood samples are determined by the method of Van Slyke (page 627). The CO_2 tensions of the gas mixtures are plotted as abscissae, the amounts of CO_2 (in ml.) liberated from 100 ml. of blood as ordinates. To study the effect of oxygenation, mixtures of hydrogen and CO_2 are used to obtain one set of data and mixtures of hydrogen (or nitrogen), oxygen, and CO_2 for another; the tension of oxygen in the latter series should be sufficient to saturate the hemoglobin with oxygen (i.e., 100 mm.).

Typical CO_2 dissociation curves are shown in Fig. 251. Here a curve for the CO_2 taken up by a sodium bicarbonate solution of strength comparable with the bicarbonate of normal blood (0.02 molar) and a curve for the amount of CO_2 taken up in physical solution are also shown.

The most important feature of the curves for blood is that the amount of CO_2 taken up by blood increases as the CO_2 tension is increased, and the slope is much steeper than the curve representing CO_2 dissolved in the plasma. Clearly the blood has a reserve capacity for combining chemically with more CO_2 than it is usually called upon to take up in the body. When the CO_2 tension is reduced, the blood gives off CO_2, and at zero CO_2 tension (as in a vacuum) blood readily gives up all of its CO_2. The bicarbonate solution, on the other hand, combines with all the CO_2 with which it can enter into chemical combination at a tension considerably below 10 mm.; above this tension all of its alkali exists as bicarbonate ($BHCO_3$) and there is no carbonate (B_2CO_3); at zero CO_2 tension

half of the $BHCO_3$ is decomposed to yield water and CO_2, but the remainder is present as B_2CO_3 and no more CO_2 can be obtained from the solution unless acid is added to decompose the carbonate. At tensions of CO_2 above 10 mm. the bicarbonate solution takes up more CO_2 in solution but does not combine with any more, so that the curve is parallel to that representing CO_2 in physical solution. The decomposition of a bicarbonate solution to liberate CO_2 according to the reaction: $2\,BHCO_3 \rightarrow B_2CO_3 + CO_2 + H_2O$ takes place quite slowly even in vacuo, several minutes being required for the reaction to be completed, and even then only half of the CO_2 is liberated. Blood, on the other hand, liberates all of its CO_2 in vacuo. This is because the hemoglobin acts as an acid and decomposes the bicarbonate. But this reaction would be comparatively slow if it were not for the enzyme *carbonic anhydrase* which Roughton and his collaborators[137] have found within the erythrocytes. This enzyme accelerates more than a thousand fold the velocity of the reaction: $CO_2 + H_2O \rightleftharpoons H_2CO_3$.

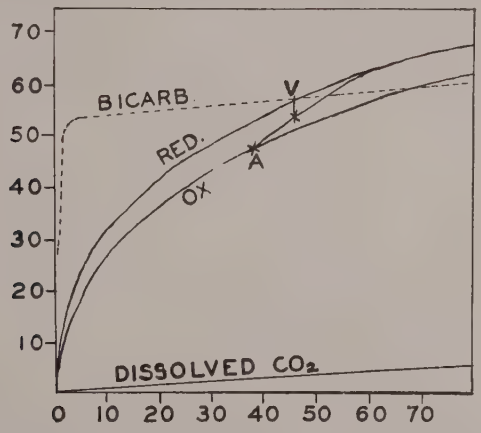

Fig. 251.—Dissociation curves for CO_2 in human blood. Abscissae, CO_2 tension (mm. Hg). Ordinate, CO_2 evolved in vacuo (ml. per 100). *Red.*, completely reduced blood (equilibration against nitrogen and CO_2). *Ox*, oxygenated blood (O_2 tension 100 mm.). *A*, point corresponding to CO_2 and O_2 tensions in arterial, and *V*, in venous blood, in the body. Bicarbonate solution 0.02 molar. (Modified from Peters and Van Slyke.)

The catalytic property is peculiar to the enzyme and is not due to the hemoglobin itself, as was once supposed. The direction of the reaction is determined by the relative masses of the substances participating in it—in this case by the tension of CO_2 in the plasma. As the CO_2 tension is raised, the gas diffuses into the erythrocytes, more H_2CO_3 is formed, and from this bicarbonate ions (HCO_3^-) are split off to combine with alkali made available by a shift of chlorine ions from the plasma into the erythrocytes. As the CO_2 tension is lowered, the reaction proceeds to the left: bicarbonate is decomposed to yield CO_2 and water, and if the CO_2 tension is reduced to zero (as in vacuo) the decomposition is complete and very rapid.

Thus we see why the total amount of CO_2 that can be taken up as bicarbonate varies directly with the tension of CO_2 to which the blood is exposed; it is important to note that most of the CO_2 enters into chemical combination, so that

the acidity of the blood is disturbed as little as possible. But just as increase in the CO_2 tension of the blood helps to turn oxygen out of it and decrease in CO_2 tension assists in reoxygenating it, so increase in the oxygen tension of the blood turns CO_2 out of it and decrease in the oxygen tension makes it capable of carrying more CO_2. This shows again the operation of the general rule that the amount of one respiratory gas carried in chemical combination in the blood varies inversely with the tension of the other gas in the plasma. The rule is illustrated by the curves shown in Fig. 251. Over the range of CO_2 tensions to which blood is ordinarily exposed in the body (40 to 50 mm.) the removal of oxygen from hemoglobin increases by about 5 ml. per 100 the ability of the blood to combine with CO_2 and the addition of oxygen decreases that ability by the same amount. This is a matter of great importance in the transport and elimination of CO_2 because it means that nearly all the CO_2 formed in the tissues

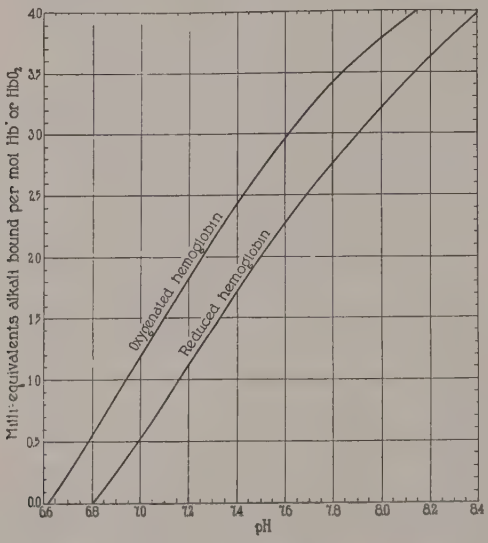

Fig. 252.—Amounts of alkali neutralized by oxygenated and reduced hemoglobin. (From Peters and Van Slyke.)

can be taken up by the blood without any change whatever in the acidity of the blood. Even more important, it means that the oxygenation of hemoglobin in the lungs is largely responsible for the liberation of CO_2 from chemical combination in the blood and its elimination into the alveolar air.

The explanation for this effect of oxygen upon CO_2 combinations is that oxygenation of hemoglobin makes the latter more acid, probably because it increases the dissociation of H-ions from one particular (oxylabile) group of the hemoglobin molecule. Hemoglobin is a protein and, like all proteins, is able to act either as an acid or as a base, depending upon the acidity of the medium; at its isoelectric point it combines with neither acid nor base. The isoelectric point of reduced hemoglobin is at pH 6.8, that of oxyhemoglobin at about pH 6.65. The blood is nearly always more alkaline, the normal pH of the blood cells being 7.25. On the alkaline side of their isoelectric points proteins behave

like acids and can combine with base; the more alkaline the medium, the more base they can bind. This can be measured by determining by titration the amount of base with which the protein can combine, and the results of such determinations with reduced and oxygenated hemoglobin are shown in Fig. 252. As the pH increases (decreased acidity) both oxygenated and reduced hemoglobin combine with more base, as would be expected, but the important point is that oxyhemoglobin always has a greater base-binding capacity than reduced hemoglobin at the same pH. At pH 7.25, which is that of the normal erythrocyte, oxyhemoglobin combines with approximately 2 equivalents of base for each molecule of oxygen taken up. When oxygen is withdrawn, the acidity of the hemoglobin molecule decreases; reduced hemoglobin can combine only with 1.3 equivalents of alkali for each molecule of oxygen given off. This is the main reason why at a given pH reduced hemoglobin can combine with more CO_2 than can oxyhemoglobin. In the lungs the oxygenation of hemoglobin increases its acidity and alkali is withdrawn from combination with bicarbonate to recombine with the hemoglobin itself. Thus for every molecule of oxygen that is given up to the tissues 0.7 molecule of CO_2 can be carried without any change in the pH of the blood. And for every molecule of oxygen taken up by hemoglobin in the lungs 0.7 molecule of CO_2 is liberated from combination with bicarbonate.

At a respiratory quotient $\left(\frac{CO_2 \text{ formed}}{O_2 \text{ consumed}}\right)$ of 0.7 the entire amount of CO_2 produced by the tissues can be taken up and eliminated from the lungs by means of the readjustments produced in the hemoglobin molecule by the removal of oxygen in the tissues and reoxygenation in the lungs. This is a low respiratory quotient: 0.8 is the usual normal one, and quotients of 1.0 are found normally. Consequently there will usually be an excess of CO_2, ranging from 0.1 to 0.3 molecule for each molecule of oxygen consumed, which must be transported and eliminated. The excess can be carried as bicarbonate only if more alkali is withdrawn from hemoglobin or from the plasma proteins. This actually occurs, and the venous blood is more acid than arterial because of it. When exercise is so severe that lactic acid enters the tissue fluid and blood in significant concentration, the respiratory quotient may temporarily rise as high as 2.0. Under such circumstances the excess CO_2 (as well as the lactic acid) is partly neutralized by additional base withdrawn from hemoglobin (which is thereby made to yield more of its oxygen than otherwise), and the venous blood now becomes definitely more acid; at rest the pH of venous blood is 0.03 less than arterial blood, but after violent exercise the difference may be 0.4 or more.

The direct combination of CO_2 with hemoglobin as carbamate is also a reversible reaction: $RNH_2 + CO_2 \rightleftharpoons RNCOOH$. The nature of this reaction is such that its direction is entirely determined by the oxygenation or reduction of the hemoglobin molecule and not by changes in CO_2 tension, which, over the range found in the body, have only a negligible effect upon the amount of CO_2 so combined. When hemoglobin loses oxygen and becomes a weaker acid, its NH_2 groups can bind more CO_2; conversely when reduced hemoglobin takes up oxygen and becomes a stronger acid, its NH_2 groups have less ability to bind CO_2. This carbamate or carbamino-bound CO_2 must not be confused with bicarbonate-bound CO_2 even though most of the alkali for the latter comes from hemoglobin. No enzyme is concerned in the carbamate reaction, but it is intrinsically a very rapid one (Roughton).

The transport of CO_2 may be summarized as follows: Arterial blood (CO_2 tension 40 mm.) is exposed in the tissue capillaries to a higher CO_2 tension and the gas diffuses rapidly into the plasma; it probably does so as dissolved CO_2, not as carbonic acid or bicarbonate which can diffuse through membranes only if a corresponding number of cations diffuse in the reverse direction; there are not enough free cations in the blood or tissues to allow this to occur rapidly and if the CO_2 produced by the tissues were in the form of carbonate or bicarbonate before it entered the blood the transport of CO_2 from the tissues would probably be far too slow for the welfare of the organism (Roughton). As a result of the diffusion the CO_2 tension of the plasma immediately rises and CO_2 diffuses into the erythrocytes. There the reaction, $CO_2 + H_2O \rightleftharpoons H_2CO_3$, catalyzed by carbonic anhydrase, at once proceeds to the right, more bicarbonate ions are formed and they diffuse out into the plasma; in exchange chlorine ions diffuse from the plasma into the erythrocyte and base is thus made available to balance the bicarbonate ions in the plasma. Simultaneously oxygen is liberated from hemoglobin, mainly (80 to 90 per cent) because the oxygen tension of the tissues is lower (40 mm.) than that of the arterial blood (90 mm.), partly (10 to 20 per cent) because the increase in CO_2 tension of the blood makes it more acid and so decreases the ability of hemoglobin to hold oxygen. Reduced hemoglobin is a weaker acid than oxyhemoglobin, to the extent that 0.7 molecule of base is released for each molecule of oxygen that is given up; this base takes up chlorine which diffuses in from the plasma, and base is thus made available in the plasma to combine with the newly formed bicarbonate. The prompt formation of bicarbonate from CO_2 reduces the CO_2 tension and permits more CO_2 to diffuse into the erythrocyte where it is transformed almost instantaneously into H_2CO_3 and thence to bicarbonate. At the same time the amount of CO_2 that can be held in carbamino combination is increased when oxygen leaves hemoglobin. All these reactions reach an equilibrium at the CO_2 tension existing in venous blood (46 mm. at rest, 60 mm. or more during exercise); they are all rapid enough to be practically completed during the one second or so which the blood spends in the tissue capillaries. The blood has taken up about 4 ml. of CO_2 per 100 if the subject is at rest, 10 to 15 ml. per 100 if he is exercising. The acidity of the blood has increased by about pH 0.03 at rest, pH 0.1 or more during exercise.

When the venous blood reaches the lungs, all these processes are reversed. The CO_2 tension of the blood (46 mm.) is higher than that of the alveolar air (40 mm.) and CO_2 immediately diffuses out of the plasma into the alveoli. This starts the reaction $CO_2 + H_2O \rightleftharpoons H_2CO_3$ in motion toward the left within the erythrocytes (carbonic anhydrase) because the reaction had come to an equilibrium at a CO_2 tension of 46 mm.; CO_2 is liberated from the bicarbonate within the erythrocytes and the gas promptly diffuses out into the plasma and thence across the alveolar membranes. Simultaneously oxygen has diffused into the plasma (oxygen tension 40 mm.) from the alveoli (oxygen tension 100 mm.) and thence into the erythrocyte; hemoglobin takes up oxygen and becomes a stronger acid. For each molecule of oxygen taken up 0.7 molecule of base is reappropriated by the hemoglobin molecule. A corresponding number of chlorine ions diffuse out into the plasma. This enables an equal number of bicarbonate ions to diffuse into the erythrocyte where they are instantly broken up (carbonic anhydrase) to yield more CO_2 which promptly diffuses out again. The carbamino-bound CO_2 is diminished because the NH_2 group to which it is attached

has a less firm hold upon it when oxygen is taken up by the hemoglobin molecule. The end result is that the blood loses its extra burden of CO_2 (4 ml. per 100 at rest, 15 ml. or more per 100 during exercise) and emerges from the lungs as arterial blood, with a CO_2 tension of 40 mm. at rest (slightly higher during exercise).

A diagrammatic presentation of the factors concerned in the removal of CO_2 from the blood in the lungs is given in Fig. 253. According to Roughton, the total amount of CO_2 given up by the blood in the lungs (i.e., 4 ml. per 100 ml. of blood, or 200 ml. per minute in a subject at rest with an oxygen consumption of 250 ml. per minute and a respiratory quotient of 0.8) is derived as follows:

About 10 per cent from CO_2 physically dissolved in the plasma.
About 20 per cent from carbamino-bound CO_2.

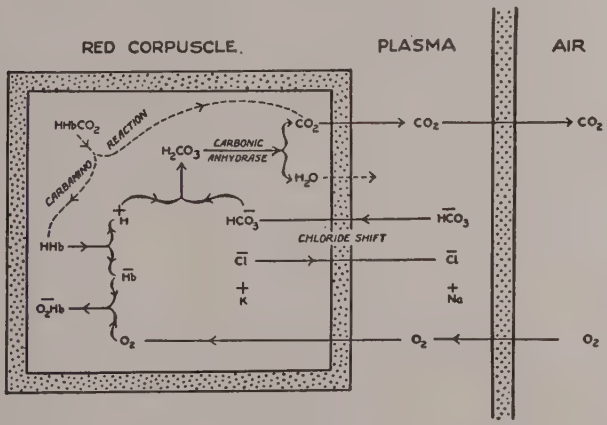

Fig. 253.—Schematic summary of the main processes concerned in the expulsion of CO_2 from blood in the lungs. *HHb*, reduced hemoglobin; *O_2Hb*, oxyhemoglobin. (From Roughton: Physiol. Rev. **15**: 241, 1935.)

About 70 per cent from bicarbonate, all of it yielded because of the action of carbonic anhydrase within the erythrocytes. Roughton calculates that about one-third of the bicarbonate is carried within the erythrocytes, two-thirds in the plasma. He believes that access of the bicarbonate ions of the plasma to the enzyme depends upon an exchange of an equal number of chlorine ions between erythrocyte and plasma; the rate at which this 70 per cent of the total CO_2 is taken up in the tissues or eliminated in the lungs would therefore depend on the rate of this shift of chlorine ions. These deductions have been recently confirmed by Stadie and O'Brien.[153]

THE REGULATION OF THE REACTION OF THE BLOOD

This subject is so closely related to the transport of CO_2 that it can properly be considered now. Many of the factors concerned in it have been mentioned in other parts of this book, but it is well to correlate them at this point.

The fundamental facts are these: In order that the cells of the body may function normally, they must be surrounded by a liquid environment (tissue

fluid and lymph) with a reaction slightly on the alkaline side of neutrality. This reaction is maintained constant in spite of wide fluctuations in the amounts of acid and alkali taken into the body with the food and in the amounts of acid produced by the metabolic processes of the body. The factors responsible for this constancy fall into two main groups: (1) *physicochemical,* and (2) *physiological.* The various factors of the two groups cooperate in such ways that a change in one physico-chemical factor is compensated ("buffered") by other factors of the same group, and if this proves insufficient physiological factors are brought into activity to restore the reaction of the blood to normal.

The range of the reaction of the blood serum compatible with life in man appears to be about from pH 7.0 to pH 7.8, but these are the extreme limits encountered in very abnormal conditions. In normal persons the range is much narrower; i.e., the acidity of the serum varies only between pH 7.4 and pH 7.6; under ordinary circumstances the serum remains at about pH 7.4, and if alkalosis is produced (as by overventilation) symptoms of that disturbance (tetany) appear when or before pH 7.6 is attained.

The Physicochemical Factors.—When a weak acid such as carbonic or phosphoric or a protein exists in solution together with its alkali salts the mixture has the property of taking up H^+ or OH^- ions, i.e., of preventing changes in the pH of the solution, when acid or alkali is added. These are *buffers.* The buffers of importance in the body are dissolved CO_2 and bicarbonate $\left(\frac{CO_2}{BHCO_3}\right)$,* diacid and dibasic phosphate $\left(\frac{BH_2PO_4}{B_2HPO_4}\right)$, and proteins and alkali proteinate, hemoglobin being by far the most important of the protein buffers $\left(\frac{HHb}{BHb}\right)$. All of the powers of the body to neutralize acid reside in these buffers; the salts of strong acids (chlorides, sulfates, etc.) are not available for the purpose because such acids have too strong an affinity for the combined base to part with it under any conditions compatible with life, and free alkali cannot exist in the body. Since all the buffer groups are necessarily mixtures of acid and base it is proper to use the term acid-base balance of the blood as a synonym for the physicochemical defense against changes in its normal reaction. Of the factors concerned in the acid-base balance the $\frac{CO_2}{BHCO_3}$ equilibrium is by far the most important, both quantitatively (it can neutralize more than 60 per cent of any acid other than carbonic, though it cannot of itself neutralize CO_2) and qualitatively (because the acid is volatile and its elimination from the body is adjusted through the respiratory center according to the tension of CO_2 in the blood). Consequently the amount of bicarbonate in the blood gives a trustworthy picture of the amount of alkali available to neutralize acid, i.e., the alkali reserve. It can be determined simply and accurately by equilibrating the blood against alveolar air (CO_2 tension = 40 mm.) and determining the amount of CO_2 contained in the blood by means of the Van Slyke apparatus.

*The situation with regard to CO_2 is peculiar. CO_2 is not an acid in itself since no hydrogen ions can arise from it. Yet it is now known that true carbonic acid (H_2CO_3) represents only about 1/1000 of the total free CO_2 of a solution of the gas in water or blood. It is also known that H_2CO_3 is a powerful acid (about as strong as acetic) whereas CO_2 is not acid at all. Formerly all of the dissolved CO_2 was thought to be as H_2CO_3, and this was supposed to be only about 1/1000 as strong as true carbonic acid is now known to be. No misunderstanding need arise if we let the symbol CO_2 represent total free CO_2, of which only about 1/1000 is in the form of H_2CO_3; from this small proportion come the hydrogen ions responsible for the acidity and buffer properties of the mixture.

If a nonvolatile acid appears in the blood, it immediately reacts with bicarbonate as follows: $HCl + NaHCO_3 = NaCl + H_2CO_3$. An increase in the amount of carbonic acid starts the reaction $CO_2 + H_2O \rightleftharpoons H_2CO_3$ in motion to the left and the excess becomes CO_2; the sodium salt is neutral. The CO_2 is promptly excreted by the lungs. Other acids are eliminated by the urine, and this process takes more time. At the normal plasma pH of 7.40 the proportions of $\frac{CO_2}{BHCO_3} = \frac{1}{20}$. The introduction of a fixed acid reduces the amount of $BHCO_3$ and this would make the blood more acid, but as soon as this happens the CO_2 tension increases and breathing is stimulated. CO_2 is thus removed until the ratio $\frac{CO_2}{BHCO_3}$ again becomes $\frac{1}{20}$; although the actual amounts of $BHCO_3$ may now be considerably less than before, as long as the ratio remains unchanged the pH is unaltered. Chlorine ions diffuse into the erythrocytes whenever the number of other anions in the plasma increases, and this makes base available in the plasma for combination with the newly introduced acid. Hemoglobin yields more of its oxygen at a given oxygen tension if the acidity of the plasma is increased, and this releases more alkali from combination with hemoglobin. The phosphate buffers and the plasma proteins can yield only negligible amounts of alkali for combination with a foreign acid.

Ordinarily fixed acids do not appear in the blood in significant amounts; it is only during violent exercise (lactic acid), severe diabetes (β-oxybutyric and acetoacetic acid), starvation (the same acids as in diabetes), or severe anoxemia (lactic acid) that fixed acids appear in sufficient quantity to deplete the alkali reserve by combining with the base of bicarbonate to form salts that are excreted in the urine. Under normal conditions CO_2 is the only acid with which the blood has to deal in appreciable quantities, and always there is more of this than of any other acid. The reactions concerned in dealing with CO_2 formed in the tissues are as follows:

1. Combination with NH_2^- groups of hemoglobin.
2. Combination with base derived from the reduction of oxyhemoglobin.
3. Combination with base made available by a shift of chlorine ions from plasma into erythrocytes.
4. Combination with base derived from the phosphate buffers:

$$H_2CO_3 + Na_2HPO_4 \rightleftharpoons NaHCO_3 + NaH_2PO_4.$$

Actually phosphates are present in the blood in such minute amounts that they cannot have more than a negligible buffer action. In the urine they are concentrated and are much more important.

5. Combination with blood proteins other than hemoglobin:

H_2CO_3 + NaProteinate $\rightleftharpoons$ $NaHCO_3$ + H-Proteinate. This also is negligible.

According to Peters and Van Slyke (page 894) the alkali available for the neutralization of acids other than carbonic is distributed among the buffer groups of the blood as follows:

	MILLIEQUIVALENTS PER LITER
Bicarbonate alkali	18
Hemoglobin alkali	8
Other buffer alkali	2
Total	28

The serum proteins can yield about 1.7 milliequivalents of alkali per liter when the pH is reduced from 7.4 to 7.0, so that most of the "other buffer alkali" is furnished by them. Counting the circulating blood volume as a little more than 5 liters, the physiologically available alkali of the blood should be able to neutralize about 150 ml. of acid of 1N strength.

The great importance of bicarbonate as a defense against acid depends upon the fact that when another acid is introduced and bicarbonate is decomposed, its acid radical can be eliminated promptly by the lungs. For this reason as much as 80 per cent of the bicarbonate of the blood can be decomposed before severe acid poisoning results. But when the acid is carbonic—as it normally is—hemoglobin is the buffer of paramount importance.

The Physiological Factors.—The important agencies in this connection are the pulmonary ventilation and the renal output of acid and base.

The *pulmonary ventilation* is closely adjusted according to changes in CO_2 tension of the arterial blood. When there is a reduction in the denominator of the fraction $\frac{CO_2}{NaHCO_3}$ because of introduction of an acid other than carbonic, the hydrion concentration of the blood increases and the CO_2 tension rises. Breathing is at once stimulated and remains so until the numerator (CO_2) is reduced to correspond with the reduction in the denominator ($NaHCO_3$); when the ratio is again 1:20 (it may now be 0.5:10 or even 0.25:5) the CO_2 tension is restored and breathing quiets down again. If the acid responsible for the change is CO_2, the numerator of the fraction increases first, but the denominator is also increased by alkali made available by the passage of chlorine into the erythrocytes; breathing is again stimulated, but it returns to normal when the ratio of carbonic acid to bicarbonate is again 1:20, though this may now mean a ratio of 1.5:30 or 2:40. Conversely, when alkali is introduced into the blood, breathing is depressed until enough CO_2 is retained to restore the ratio to the normal 1:20; if CO_2 is lost (as at high altitudes or in any hyperpnea due to something other than increased CO_2 tension in the blood) there is a relative excess of $NaHCO_3$, and this is taken care of at least in part by excretion of an alkaline urine.

The *kidney* compensates mainly by altering the balance between the acid (NaH_2PO_4) and basic (Na_2HPO_4) phosphates excreted in the urine. On an ordinary mixed (meat-containing) diet the urine is acid, i.e., there is a relative excess of NaH_2PO_4. On a vegetable diet the urine is alkaline, Na_2HPO_4 being in excess. Whenever there is an excess of acid in the body the NaH_2PO_4 is excreted in larger proportion and when there is an excess of alkali the Na_2HPO_4 predominates; as we have just seen, this takes place at high altitudes and under any other condition in which overventilation occurs.

The ammonia mechanism makes NH_3 available for combination with abnormal acid, as in the acidosis of diabetes, instead of excreting the nitrogen as neutral urea. The ammonia neutralizes acid that would otherwise demand alkali of the blood and the latter is thus spared to some extent. When there is a relative excess of alkali in the blood, ammonia excretion diminishes or ceases and other alkali is excreted instead. This mechanism comes into play very slowly, i.e., after several days of acidosis or alkalosis.

Acidosis and Alkalosis.—The mechanisms which we have just considered are so effective that ordinarily the hydrion concentration and bicarbonate content of the blood remain remarkably constant, the former at about pH 7.4, the

latter at a plasma CO_2 combining capacity of about 60 ml. per 100. There may be temporary changes associated with muscular activity, ingestion of acid or alkali, or voluntary interferences with normal breathing, but these are fully and promptly recovered from by normal persons. In a number of diseases, however, the body defenses against poisoning by acid or alkali are strained more or less severely and if they break down *acidosis* or *alkalosis* results. Both are abnormal and both (unless produced intentionally for experimental purposes) are serious. *Acidosis* means excess acid in the body, *alkalosis* signifies excess alkali. Strictly speaking, acidosis is present only when the blood is less alkaline than normal (pH below 7.4) and alkalosis when the blood is more alkaline than normal (pH above 7.4). Actually, however, there may be sufficient poisoning by acid or alkali excess to produce definite symptoms before the reaction of the blood has changed. As long as the hydrion concentration of the blood remains within normal limits, the acidosis or alkalosis is *compensated*. When the poisoning becomes too severe for the defense mechanisms to compensate and the hydrion concentration changes, the acidosis or alkalosis is *uncompensated* and the condition is usually a very serious one.

We have seen that the maintenance of the hydrion concentration of the blood depends upon a balance between weak acids and their alkali salts (CO_2-bicarbonate, hemoglobin-hemoglobinate, diacid-dibasic phosphates, protein-proteinate), for it is only such mixtures that can act as buffers. As already pointed out, to speak of the *acid-base balance of the blood* is the equivalent of listing the physicochemical reactions concerned in the regulation of the reaction of the blood. Acidosis then becomes a disturbance of the acid-base balance toward the acid side, alkalosis a disturbance toward the alkaline. But a disturbance toward the acid side may be due either to a primary excess of acid or to a primary deficiency of alkali; as the condition occurs clinically both factors usually are involved simultaneously. Similarly a disturbance toward the alkaline side may result from a primary excess of alkali or from a primary deficiency of acid; clinically the latter is the more frequent cause. We have seen that the $\frac{CO_2}{NaHCO_3}$ buffer system is the first and most important defense of the body against poisoning by acid (other than carbonic) or alkali because changes in bicarbonate lead to compensatory changes in the elimination of CO_2 by the lungs and the ratio of acid to base is thus readily restored. Consequently the amount of bicarbonate in the blood gives a direct and accurate picture of the status of the acid-base balance in general and the amount of bicarbonate (measured by the capacity of the blood to combine with CO_2) decreases in acidosis and increases in alkalosis, provided that the acidosis or alkalosis is due to changes in acid or alkali other than CO_2 itself. If an acidosis is due primarily to retention of CO_2 the blood bicarbonate increases, and if an alkalosis is due primarily to excessive loss of CO_2 the bicarbonate decreases.

A definite change in the bicarbonate content of the blood usually occurs long before the hydrion concentration has become abnormal. Because this change occurs early and is easily detected in changes in the CO_2 combining power of the blood plasma, most clinical states of disturbance in the acid-base balance of the blood can properly be classified as conditions of *alkali deficit* or *alkali excess*. The corresponding disturbances due primarily to retention or loss of CO_2 must be kept distinct, however, and classified as states of CO_2 excess or CO_2

deficit. A *compensated alkali deficit* is one in which the loss of bicarbonate is balanced by increased elimination of CO_2 and the hydrion concentration of the blood is unchanged; a *compensated alkali excess* represents a corresponding retention of enough CO_2 to keep the blood reaction from becoming abnormally alkaline. An *uncompensated alkali deficit* is present when the reduction in bicarbonate is too great to be counteracted by increased elimination of CO_2 and the blood becomes more acid; an *uncompensated alkali excess* is produced by absorption of too much alkali, or loss of too much acid, to be counteracted by retention of CO_2, and the blood is abnormally alkaline.

Primary alkali deficit is the commonest type of abnormality of the acid-base balance. It is seen in characteristic form in the acidosis of diabetes mellitus or advanced nephritis. In diabetes the primary factor is excess of abnormal fixed acids (β-oxybutyric, acetoacetic) resulting from incomplete oxidation of fats; these combine with the alkali of the blood and the combinations are excreted in the urine. The bicarbonate of the blood is thus reduced. At the same time the output of urine is increased because of the increased amount of material to be eliminated, and ammonia excretion is also greatly increased; the body loses salts and water and becomes dehydrated. Thus in this condition there is both acid excess and alkali deficit, but the former is the primary factor. In nephritis the kidney is unable to excrete the fixed acids normally formed in metabolism and their retention leads to reduction in the bicarbonate of the blood. Experimentally a condition corresponding to primary alkali deficit can be produced by ingestion of large amounts of acid-forming salts such as ammonium chloride (15 to 20 grams) or calcium chloride (25 to 30 grams) (the ammonia becomes urea in the body and an excess of Cl is thus created; Ca is excreted by the intestines leaving the Cl behind in the blood). In all such cases, clinical and experimental, the outstanding symptom is dyspnea; there is also polyuria and the ammonia excretion in the urine increases. In terminal diabetic acidosis respiration becomes more and more dyspneic and finally takes on the agonal character known as "air hunger." In starvation there is an acidosis similar to that of diabetes and due to the same cause, i.e., incomplete combustion of fats. Acidosis also occurs in poisoning by methyl alcohol (CH_3OH), which is oxidized to formic acid (HCOOH) in the body and the latter is excreted in the urine in combination with alkali (HCOONa). An acidosis similar to that of diabetes (ketosis) is sometimes produced intentionally by a special ketogenic diet in the treatment of epilepsy, the seizures of which have been found to be reduced in some subjects by this procedure.

Primary alkali excess is encountered clinically only as the result of loss of acid from the body, as in the vomiting of pyloric or intestinal obstruction (HCl is lost in the vomited gastric contents); in some cases of infantile diarrhea there may be a relatively greater loss of acid than of alkali, while in others the reverse may be true; i.e., either alkali excess or alkali deficiency may result, the urine being alkaline in the first case, acid in the second. Alkali excess can of course be produced by ingestion of alkali. The result of primary alkali excess is the same no matter how it is produced: there is an increase in the bicarbonate of the blood, breathing is apt to be depressed, or at least the breath can be held for an unusually long time, alveolar CO_2 tension tends to rise, the urine becomes alkaline and its ammonia content decreases; if the blood becomes definitely alkaline (pH 7.6) tetany is likely to occur.

Primary CO_2 excess is unimportant practically. It can occur in disease only when the gas exchange is markedly interfered with, and then the anoxia which occurs simultaneously is much the more serious condition. It may of course be produced intentionally by inhalation of CO_2 either for experimental purposes or to combat respiratory depression. It occurs when the respiratory center is depressed by narcotics (morphine, ether, alcohol, barbiturates, etc.) but breathing continues only because the CO_2 tension of the blood rises and the O_2 tension falls; the anoxia is the dangerous feature, not the CO_2 excess (see Chap. XLIV). Peters and Van Slyke state that "It is doubtful that (medical and lay literature) contains any case of death due primarily to impaired respiratory ability to excrete carbonic acid."*

Primary CO_2 deficit occurs whenever respiration is driven by some agent other than the normal chemical stimulus (carbon dioxide tension in the center). Thus it results from the hyperpnea of anoxemia (as at high altitudes), of fever, or of high temperature produced by external heat; it is occasionally seen in encephalitis when respiration is increased for long periods of time presumably because the disease involves excitation of the cells of the center. In all such cases the CO_2 tension of the blood is reduced and the blood tends to become more alkaline; if the latter change proceeds far enough (to pH 7.6) tetany may occur. The urine becomes more alkaline due to increased excretion of base, and the blood bicarbonate falls; this is the main compensatory factor, and it usually succeeds in restoring the pH of the blood nearly if not quite to normal.

*The rapidly increasing use of solidified CO_2 ("dry ice") carries with it hazards which have long been recognized by miners and well-diggers but of which the general public is still unaware. The United Press on November 25, 1936, distributed an account (see the Philadelphia Inquirer of that date) of the death in New York of 5 men who were overcome by "dry ice" fumes while unloading frozen cherries from the hold of a ship; two others recovered. Accidents of this nature have often happened in mines and in wells and it has long been known that CO_2 accumulates in low, poorly ventilated places because it is heavier than air. When there is a high proportion of CO_2 in the inspired air, the individual exposed to it is in danger both from the narcotic effects of CO_2 (see page 563) and from the anoxemia resulting from reduction in the proportion of oxygen in the air. Volatilization of solidified CO_2 in a poorly ventilated space will lead to a marked rise in the CO_2 content of the air, particularly near the bottom of the space, thus reproducing the conditions which are found in mines as a result of the oxidation of coal or other organic material, in wells as a consequence of fermentations and oxidations carried out by plants, molds, and bacteria.

CHAPTER XLIV

ABNORMAL TYPES OF RESPIRATION

Our considerations of the control of respiration, hitherto confined to the normal state, have now proceeded far enough to warrant an attempt to apply them to the various conditions in which an abnormality of breathing is a matter of concern either to the afflicted person or to those attending him. Obviously it is under the latter circumstances that the practical importance of these considerations is greatest, and as far as the practicing physician is concerned the ensuing section is the climax of respiratory physiology. I believe that our understanding of the factors that may contribute to respiratory control has advanced sufficiently to permit us now to approach this subject by deriving first from theoretical grounds the abnormalities that might be expected and then to cite actual examples of these as they occur in the course of disease; this is the viewpoint from which the following section has been compiled.

DYSPNEA

According to Meakins, "Dyspnea is the consciousness of the necessity for increased respiratory effort." The outstanding feature is therefore an element of discomfort, usually a sensation of breathlessness, on the part of the subject. In terms of our present understanding of the interplay of factors operating in the respiratory center (page 601), this means that the discharge of impulses by the inspiratory neurons does not diminish or disappear as it should at the end of inspiration but persists throughout the respiratory cycle and the desire to breathe therefore is not satisfied even by abnormally powerful respiratory efforts. As far as objectively demonstrable characteristics are concerned, *dyspnea* (labored breathing) differs from *eupnea* (quiet breathing) in that the accessory inspiratory and the expiratory muscles participate actively in the respiratory act during dyspneic breathing (page 556). *Hyperpnea* (hyperventilation) is a related term denoting simply an increase in pulmonary ventilation without commitment as to subjective sensations or character of breathing.*

Theoretically dyspnea might be due to any one or more of the following factors: (1) increase in the chemical stimulus acting on the center; (2) in-

*It may be well to direct the reader's attention to some of the difficulties involved in the literal acceptance of these definitions, for the vexatious problem of terminology in physiology is well illustrated here. According to Meakins' definition, as Christie[35] points out, dyspnea could not occur in comatose or anesthetized subjects, and even greater absurdities may result unless the definition is accorded reasonable flexibility (see Christie[35]). The distinction between dyspnea and hyperpnea can be based only upon subjective factors; since the accessory inspiratory and expiratory muscles are active in both conditions the difference between hyperpnea and dyspnea must either be made on an arbitrary basis of degree of increase in respiratory activity or in terms of the subject's sensations. Dyspnea can occur without increased pulmonary ventilation; reduction of the latter is in fact a common cause of dyspnea (see below). On the other hand, increased ventilation can be produced by artificial means without discomfort, as by artificial respiration or intratracheal insufflation; subjects who have been in the Drinker respirator (page 706) describe the sensations as being entirely pleasant when pulmonary ventilation is thus artificially carried out even though the ventilation is so excessive that the respiratory neurons are inactive and there is no desire to breathe. Thus dyspnea and hyperpnea are not synonyms. The value of the term "dyspnea" lies, as Christie points out, in its clinical implications, and no confusion need arise if this term is always used to imply a situation in which some abnormality of the respiratory system (in the broad sense—page 534) has become severe enough to arouse concern on the part either of the subject or of the observer. Hyperpnea should be restricted to voluntarily or artificially induced respiratory reactions.

crease in the excitatory nerve influences to the center; (3) increased excitability of the center; (4) decrease in the mechanical efficiency of the respiratory act; (5) adverse changes in the circulation, either in the lungs or in the center. As will be seen, examples of each of these may be encountered clinically; the reader will find the ensuing section easier to understand in terms of the general schemes of the entire respiratory process (page 535) and of the interaction of central and reflex factors in the control of breathing (page 601).

1. **Dyspnea Due to Increase in the Chemical Stimulus Acting on the Respiratory Center.**—In this category we find any dyspnea resulting from an increase in the carbon dioxide tension in the arterial blood. This can occur from retention of the carbon dioxide produced in the body whenever the pulmonary gas exchange is interfered with (i.e., in *asphyxia*), but in such cases anoxemia will also be present and will contribute (through chemoreceptor reflexes) to the respiratory response. Dyspnea due entirely to increased CO_2 tension can of course be produced by inhalation of air or oxygen enriched with CO_2 (Fig. 214, page 541), but even here chemoreceptor reflexes would play a part in any except mild effects.

In the dyspnea of acidosis increased carbon dioxide tension probably accounts for much or all of the effect in the early stages (i.e., in *compensated* acidosis; see page 645); when the condition is more severe and the hydrion concentration of the blood increases (*uncompensated* acidosis) chemoreceptor reflexes probably come into play, and these may be entirely responsible for the agonal, "air-hunger" type of dyspnea seen in extreme acidosis. In most cases of dyspnea occurring in the course of disease in man (excepting terminal states when breathing is failing) the carbon dioxide tension of arterial blood is below the normal level.

2. **Dyspnea Due to Increase in the Excitatory Nerve Influences to the Respiratory Center.**—Even now we can place under this category a larger proportion of clinical cases of dyspnea than under any other, and future developments are likely to add to these at the expense of the others until eventually perhaps all forms of dyspnea in disease will be explained on this basis. Here we must include:

a. *Reflexes From the Carotid and Aortic Chemoreceptors.*—Since these account for some of the dyspnea produced by rising CO_2 tension in the blood, and probably for all of that elicited by arterial anoxemia (page 586), it is clear that this is a major factor in the dyspnea of asphyxia however elicited. Asphyxia may be produced by inhalation of air that is abnormally rich in CO_2 or abnormally poor in oxygen (as in wells or mines, or during anesthesia by nitrous oxide or ethylene, or at high altitudes, CO_2 being of course not abnormally high in the latter cases). It may result from obstruction to the free movement of air in and out of the lungs because of inflammatory or neoplastic processes, exudates or secretions, foreign bodies, occlusion of the glottis for any cause, abnormal contraction of the bronchial muscles (asthma), encroachment on the lumen of the finer air passages by engorged blood vessels, or partial or complete paralysis of the respiratory muscles. It may also result from interference with the free diffusion of gases between the air and the blood in the lungs, either because of reduction in the available surface (by rupture, collapse, adhesion, or consolidation of alveoli, or occlusion of pulmonary blood vessels), or because of decreased permeability of the membrane by reason of actual thickening or the introduction of an abnormal layer of fluid

(as in certain forms of pneumonia and in congestive heart failure). Apart from asphyxia, the dyspnea of acidosis may also be due partly (or even entirely) to chemoreceptor reflexes. Perhaps this is also true of the dyspnea associated with fever, but the experimental evidence in support of this is at present quite scanty (page 591), and the idea must be viewed as highly speculative. Finally, the dyspnea encountered in poisoning by cyanides, sulfides, nicotine, lobeline, coniine, etc., is referable entirely to chemoreceptor reflexes.

b. *Reflexes From the Lungs.*—Whenever the alveoli are no longer normally distended the excito-inspiratory Hering-Breuer reflex is brought into action in the undistended parts, and since the receptors are of the slowly adapting type the excitatory influence thus aroused will continue as long as the subnormal inflation persists. Thus the dyspnea of pneumothorax, and the wholly analogous effect of atelectasis produced by obstruction of a bronchus, can be accounted for. Interference with the circulation in the blood vessels in the alveolar walls (as by embolization of the pulmonary arterial branches or thrombosis on the pulmonary venous side) is followed by partial collapse of some of the alveoli, and this probably explains the marked acceleration of breathing observed by Binger, Brow and Branch[24] when they injected starch particles intravenously in dogs—an effect that they found to be abolished by blocking the vagi and to be related to decrease in the size of the alveoli amounting in some places to actual collapse. In any case, failure of the lungs (or of any considerable part of them) to expand properly with inspiration will diminish the strength of the inhibito-inspiratory influence set up by inflation of the lungs and this may account for lack of satisfaction of the urge to breathe even by the maximum inspiratory effort.

According to Christie,[35] and Harrison,[70] the dyspnea of heart disease in man is probably due to increased rigidity of the lung consequent upon pulmonary congestion. This rigidity presumably leads to continuous stimulation of the excito-inspiratory Hering-Breuer reflex and thus to the sensation of breathlessness. Most patients with congestive failure of the heart are least uncomfortable in the sitting position *(orthopnea),* which may be related to the facts that diminution in the vital capacity of the lungs is present in cardiac dyspnea and that the vital capacity is greatest in the sitting position (page 543). These observations probably are to be interpreted as follows: congestion in the pulmonary circuit (resulting from a relative insufficiency of the right ventricle) causes rigidity of the lung, which is manifested in (and can be measured at least approximately by) reduction in the vital capacity, indicating a diminution in the extent to which the pulmonary tissues are expanded at inspiration. This, through continuous stimulation of the excito-inspiratory Hering-Breuer reflex, causes dyspnea; in the upright position the vital capacity is increased and therefore (presumably) the pulmonary congestion is decreased correspondingly; the respiratory distress is diminished because the pulmonary tissues are now expanding better with inspiration, and the urge to breathe, which previously did not cease even at the height of inspiration (presumably because the alveolar ducts did not enlarge sufficiently to abolish the excito-inspiratory discharge from one set of Hering-Breuer receptors and to set up an effective inhibito-inspiratory discharge from the other), now can diminish as it normally does during inspiration, and the sensation of breathlessness (i.e., of being unable to satisfy the urge to breathe even by a maximal inspiratory effort) decreases correspondingly.*

Whether any other reflexes from the lungs or the pulmonary blood vessels play a part in dyspnea remains to be determined. If our conception of the embryological significance

*It is perhaps significant in this connection that morphine, which is notable for its ability to relieve the dyspnea of heart disease, appears also to be notable for its ability to exaggerate inhibitory reflexes to respiration.[74, 139] The action apparently is central and may be due to a primary decrease in the sensitivity of the central neurons to the chemical stimulus, but the end result is to increase the effectiveness of inhibito-inspiratory influences. This may account in part for the diminution in the breathlessness of these patients when given morphine, but the removal of unpleasant sensations for which this drug is justly famous can certainly not be overlooked as an important factor in the relief produced by it in such patients.

of the carotid and aortic chemoreceptors is valid (page 597), then the derivation of the pulmonary artery from the sixth branchial arch arteries and the demonstration by Nonidez[21] that this vessel, in newborn animals, may supply tissue having the morphological characteristics of chemoreceptors, assume deeper significance. A search for chemoreflex mechanisms that would come into play only under abnormal conditions of pressure or flow in the pulmonary circulation might disclose something of this sort as an important factor in cardiac dyspnea. At present there is no information on this subject except that reported by Daly,[45] who found some evidence of a pressoreflex system in the pulmonary artery of the dog; the reflex effects from this system seem altogether too weak to justify the belief that severe dyspnea could ever be produced by it. Reflexes from the muscles or joints of the thoracic wall may also be a factor in dyspnea, but this has not yet been demonstrated to be the case. Yet it is only fair to point out that much remains to be learned about the physiology of cardiac dyspnea and perhaps postural reflexes are more important than they are now thought to be. Wood[170, 171] has found that some of these patients are least dyspneic when lying on one side, some on the other, and some when in the face-down position. Perhaps the congestion in the pulmonary circulation is best relieved by a position that varies from individual to individual, for reasons as yet unknown; or perhaps some other reflex factors (also unknown) are involved.

3. **Dyspnea Referable to Changes in Excitability of the Central Neurons.**—As we have already seen (page 604) this factor now appears to be the dominant one in respiratory control, but it is impossible to draw any hard and fast distinction between it and excitatory reflexes. From the standpoint of the physiology of dyspnea, we may include here:

(a) *Irritative Lesions Impinging Directly Upon the Medullary Reticular Formation, or Located Elsewhere in the Neuraxis and Giving Rise to Impulses Excitatory to the Respiratory Neurons.*—This probably accounts for the hyperpnea sometimes observed in patients with encephalitis or other types of intracranial disease. Between this and the hyperpnea, breathlessness, or respiratory discomfort that may be associated with functional neuroses the only distinction is that the lesions in the latter presumably are purely biochemical or biophysical and leave no demonstrable mark in the neuraxis. The result is the same as though the excitatory impulses which normally arise only when there is need for increased pulmonary ventilation (as in exercise—page 603) were bombarding the respiratory neurons.

(b) *Increased Metabolic Rate in the Respiratory Neurons.*—This is a theoretical possibility the actual importance of which can only be conjectured (see page 568). The respiratory effect would be attributed to an increase in the number of molecules of carbon dioxide within the central neurons because of an increase in the rate at which CO_2 is being produced by them. The hyperpnea associated with increased body temperature might be due to this factor and so might that elicited by drugs and poisons which increase nerve cell activity in general (the so-called analeptics, including strychnine, caffeine, camphor, atropine, picrotoxin, metrazol, coramine, hexeton-drugs which have the common property of producing convulsions when given in sufficiently large amounts and whose actions on respiration, as far as is known, are entirely due to direct effects on the neuraxis, not to reflexes*). These drugs presumably combine with the neuronal protoplasm so as to produce the same sort of increase in excitability that carbon dioxide brings about.

The converse of this relation (depression of breathing attributable to decreased excitability of the center) is encountered in hibernating animals[128] and

*Coramine is a partial exception to this, for the hyperpnea produced by it is said to be partly due to chemoreceptor reflexes, partly to a direct central action.

in human beings in which similar processes are artificially induced by depressant drugs (see page 683) or by reducing the body temperature.[149, 150] It is probable that the fundamental factor in these cases is reduction in the metabolic rate of the cells of the neuraxis; whether the ensuing respiratory depression is due to removal of excitatory impulses previously playing upon the respiratory neurons but arising elsewhere, or to decrease in the oxidative reactions within the respiratory neurons themselves, is entirely conjectural.

4. **Dyspnea Due to Changes in the Mechanical Efficiency of the Respiratory Movements.**—This special section accommodates those dyspneas in which the chest has assumed a position close to that of full inspiration and is capable of further enlargement only by means of strong contraction of the accessory inspiratory muscles. This is the situation in *emphysema.* The breathlessness often encountered in this condition probably means that the Hering-Breuer reflex system is perverted much as it is in cardiac dyspnea, i.e., the excito-inspiratory reflex is continually active because of shortening of a considerable number of the corresponding receptors in some parts of the lungs. This could result from the breaking of alveolar septa at one end, allowing the other to retract and thus to shorten these receptors. At inspiration these parts of the lungs could not stretch enough to terminate this discharge. The inhibito-inspiratory reflex also would not be as effective as it should be both because the receptors that are active are not stretched as much as normally at inspiration (by reason of the relative smallness of the further thoracic enlargement that can be produced in an emphysematous chest), and because a considerable proportion of them would be permanently inactivated by the same alveolar changes that lead to a continuous excito-inspiratory discharge from the other set of receptors. When the movements of the chest are sufficiently interfered with to lead to inadequacy of pulmonary ventilation asphyxia of course ensues and dyspnea is then contributed to by the other factors noted above in connection with asphyxia. It is noteworthy that (according to Nielsen[119]) the cost of pulmonary ventilation in man (i.e., the fraction of the body's total oxygen consumption that is due to the activity of the respiratory muscles) is least during quiet breathing and increases sharply during dyspnea; during quiet breathing the respiratory muscles accounted for about 1.3 per cent of the total oxygen consumption, but during the dyspnea of exercise this proportion rose to 9 per cent of the total. Thus it would seem that the accessory inspiratory and the expiratory muscles are relatively inefficient compared with those of quiet breathing, and any condition in which pulmonary ventilation must be brought about entirely by them necessarily entails an undue amount of exertion.

5. **Dyspnea Due to Changes in the Circulation.**—Here we may consider all of the circulatory abnormalities that can lead to inadequate flow of blood through the lungs or tissues (particularly the respiratory center itself) as well as insufficiencies on the part of the gas-transporting medium itself (hemoglobin).

(a) *Faulty Circulation Through the Lungs.*—This condition may lead to dyspnea when it is either too sluggish or too rapid. As we have already seen, too sluggish circulation leads to engorgement of the pulmonary system, increases the rigidity of the lung, and, by the diminished respiratory excursion thus brought about, apparently gives rise to reflexes excitatory to respiration. Too rapid circulation through the lungs, on the other hand, may shorten the time permitted for the pulmonary gas exchange to the point at which anoxemia

ensues. When we recall that even under normal conditions the blood does not come to equilibrium with the alveolar air with respect to oxygen but reaches the tissues with the hemoglobin only about 95 per cent saturated with oxygen and with the arterial tension of the gas about 10 mm. lower than that in the alveolar air (Chapter XLII), it is evident that a further acceleration of the flow of blood could easily increase this discrepancy. Ordinarily when such acceleration occurs (as during exercise) it is compensated to a considerable extent by increases in the diffusion constant for oxygen (page 620) and in the alveolar oxygen tension (consequent upon deeper breathing—page 618). This is not the case in disease conditions in which, by reason of interference with the circulation through part of the pulmonary system, the intact parts of this system must accommodate a larger proportion of the total cardiac output. Even the highest alveolar oxygen tension attainable in the intact alveoli by increased breathing of ordinary air may then be inadequate. Such a situation can exist in emphysema, atelectasis, lobar pneumonia, or occlusion of the arterial or venous supply of parts of the alveolar system for any cause. The actual dyspnea in such cases would probably be referable to reflexes aroused either in the lungs by the deranged relations of the Hering-Breuer receptors, or in the chemoreceptors by the anoxemia. It is unlikely that increase in the chemical stimulus acting directly on the center would be a factor here because of the greater diffusibility of carbon dioxide than oxygen; there is much less likelihood of the blood failing to unload its CO_2 properly in the lungs than there is of its being inadequately saturated with oxygen under such circumstances, and the CO_2 tension of arterial blood would probably fall in consequence of the increased pulmonary ventilation brought about reflexly.

(b) *Faulty Circulation Through the Tissues as a Whole May Cause Dyspnea Because of the Presence of Acid Products of Incomplete Oxidation.*—Such products on entering the blood in sufficient amounts, would increase the carbon dioxide tension and thus stimulate breathing centrally (perhaps also in the chemoreceptors); if severe enough, chemoreceptor reflexes may be set up by the increased acidity itself, thus intensifying the dyspnea. Perhaps reflexes excitatory to breathing may also arise in tissues suffering from an inadequate flow of blood. The experiments of Alam and Smirk[6] strongly suggest that this can occur, but further investigation is needed before the importance of this factor can be surmised.

(c) *Faulty Circulation Through the Respiratory Center Itself.*—Dyspnea due to this factor is illustrated by the violent respiratory response of a reactive animal to abrupt occlusion of the four main arteries leading to the brain (Fig. 254); such an effect is doubtless due to sudden accumulation in the cells of the center (or in other neurons capable of setting up impulses strongly excitatory to these) of metabolic products the concentration of which becomes stimulant when the circulation suddenly becomes inadequate to carry them away as rapidly as they are formed. The clinical counterpart of this must be very rare, for dyspnea occurs in animals only if an extreme reduction in blood supply takes place suddenly and the central neurons are not greatly depressed (by narcosis, anoxia, etc.) at the time of the reduction; a similar situation would be expected in man only in cases of sudden occlusion or rupture of major arteries in the medulla. Conditions in which respiration is strongly influenced by changes in the cerebral circulation may, however, be much commoner than this. For one thing, it is not unlikely that, by interference with the venous

return from the brain, sufficient accumulation of carbon dioxide can be brought about to lead to dyspnea; this has been suggested in the past as a possible cause of cardiac dyspnea, but the burden of evidence has been against it, largely because no conclusive experimental evidence was ever presented that such a relation actually could exist. The negative outcome of experiments intended to test this probably is due to the fact that the cerebral venous system communicates freely not only with the channels leading directly from the head to the superior cava, but also with the spinal venous sinuses; since the latter are drained by numerous veins throughout the length of the vertebral canal,

Fig. 254.—Effect of acute cerebral anemia on respiration. Cat: barbital narcosis. Respiration recorded by plethysmograph, blood pressure by mercury manometer. Tracing just below blood pressure shows pressure in circle of Willis, recorded from cephalic ends of vertebral arteries, which are ligated at their cardiac ends. *A*, occlusion of carotid arteries until respiration failed. *B*, briefer occlusion. Note marked stimulation of breathing in both cases. Blood pressure usually rises more than in this animal, in which pulse slowed markedly as a result of the anemia.

occlusion of the jugular and vertebral veins, even complete ligation of the superior cava close to the heart, produces only a relatively slight grade of venous stasis in the cerebral venous system. If the communication between the cerebral and the spinal venous systems is occluded (as was done by Hendrix in unpublished experiments made in the writer's laboratory), closure of the jugular veins causes as violent a dyspnea as that produced by occlusion of the carotid and vertebral arteries (Fig. 255). The rise in general venous pressure

which is an outstanding feature in congestive failure of the heart would inevitably be associated with some interference with the venous return from the central neurons, but whether the interference would be sufficient to warrant its being held responsible for some or all of the phenomena of cardiac dyspnea and orthopnea remains undetermined.

Another set of circumstances in which the cerebral circulation can be held responsible for dyspnea is found in *rise in cerebrospinal fluid pressure,* no matter how it is brought about. When this pressure becomes equal to that in the cerebral capillaries the flow of blood in the latter ceases; the effect is exerted equally throughout the cranial cavity because the container is indistensible

Fig. 255.—Dyspnea produced by interference with the venous return from the head.

Dog anesthetized with pentobarbital. Upper record—respiration (pneumograph); next record—femoral blood pressure. Vagodepressor nerves intact. The spinal venous sinuses were ligated from a ventral approach between the first and second cervical vertebrae; the vertebral arteries and veins were also ligated at the same level. Venous return from the brain was thus thrown largely if not entirely into the jugular veins. When these were clamped (between signals) respiration was stimulated (after a latent period of about 15 seconds), maximum increase being from 17 to 36 per minute. On release of veins blood pressure (which had been falling during the occlusion) rose sharply at once, fell, then rose again (probably because of changes in cardiac filling); there was an apnea about 15 seconds after the release, followed by gradual recovery. (From unpublished experiments by J. P. Hendrix.)

and the contents are incompressible. The medullary centers react to this acute anemia with hyperpnea and hypertension in the usual manner (Fig. 256); the vasomotor response leads to rise in pressure in the cerebral capillaries to the point at which the anemia is relieved, and this continues as the cerebrospinal

fluid pressure rises until the limit of the capacity of the vasomotor center has been reached; now acute anemia again ensues, but this time there is no longer any possibility of relief by further rise in blood pressure, and the central neurons rapidly fail (page 664). The breathing associated with increased intracranial tension is typically slow and labored (dyspneic), and it may be periodic (Fig. 257). It is not unlikely that an important factor in these respiratory and vasomotor responses is the onset of chemoreceptor reflexes aroused by anoxemia during the abnormally long period between breaths, the centers being so deranged by anoxia that they are no longer normally sensitive to changes in the CO_2 tension of their own environment; the breath (or group of breaths) removes the anoxic stimulus to the chemoreceptors and breathing ceases until anoxemia again supervenes.

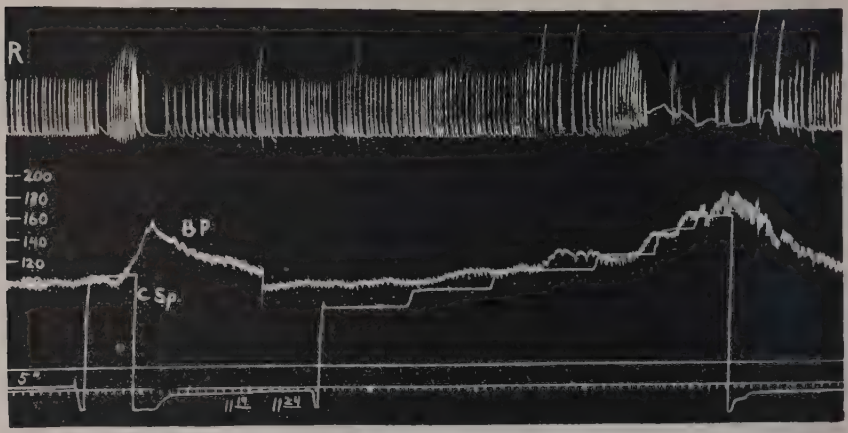

Fig. 256.—Effects of increased intracranial tension on blood pressure and respiration.

Dog anesthetized with barbital; all nerves intact; needle in cisterna magna connected through a warming coil to reservoir of saline solution that could be raised and lowered as desired. Respiration by pneumograph; blood pressure (from femoral artery) and pressure of fluid in cisterna both recorded by mercury manometers with time tracing (5-second intervals) as base line.

At left: sudden rapid elevation of cerebrospinal pressure (*C.Sp.*) to a level higher than arterial blood pressure (*BP*) evokes hyperpnea and hypertension.

Then cerebrospinal pressure was raised in steps, blood pressure rising with it and respiration showing stimulation until intracranial tension has risen to about 150 mm. Hg, when respiration ceases (except for a few feeble gasps); vasomotor center evidently was more resistant than respiratory center.

This brings us to the question of *periodic breathing* in general. The commonest form is Cheyne-Stokes respiration (Fig. 258), which is characterized by respiratory efforts that are at first weak but become successively stronger until definite dyspnea is present;[158] following this, breathing gradually diminishes until apnea occurs. It is noteworthy that the breathing, when it occurs, becomes dyspneic and for this reason we may consider the subject at this time.

The cyclic changes in respiratory activity are accompanied by changes in consciousness (which is clouded or absent during the apnea, improves as the breathing becomes more active, is nearest normal during the dyspnea, and fades as the breathing diminishes) and in blood pressure (which is usually though not always lowest at the time of apnea and highest during the dyspnea).

Cheyne-Stokes breathing is an ominous sign in disease, not because it is dangerous in itself, but because it is a signal of severe anoxia in the central nervous system. It is encountered in decompensated heart disease, in uremia, and in cases of disease or injury involving the brain. It may be seen in normal persons at high altitudes and has been described in aviators and mountain climbers, in the latter when asleep, in the former when they ascend rapidly and before consciousness is lost completely. Haldane and his collaborators[67] were able to produce it at will by subjecting themselves to anoxemia. It can also be produced in normal individuals by excessive overbreathing, as we have already seen (page 609). Finally, it is not uncommon in infants, especially in those born prematurely, and in these the apneic periods may be dangerously long.

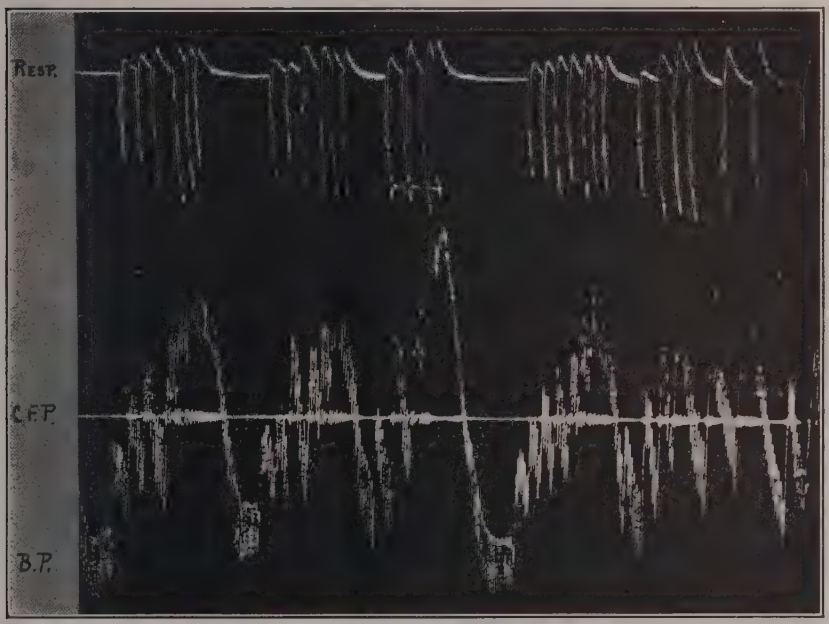

Fig. 257.—Periodic breathing due to increased intracranial pressure. Dog: arterial blood pressure (B.P.) and intracranial pressure (C.F.P.) recorded by mercury manometers set at same base line. Note breathing as arterial pressure rises above intracranial pressure, apnea as it falls below the latter. (From Eyster: J. Exp. Med. 8: 565, 1906.)

Cheyne-Stokes breathing is most probably due to anoxia in the brain in all cases; in newborn infants additional factors to be considered are injury during birth and congenital imperfection in the sensitivity of the respiratory neurons. The coincidence of improved consciousness with respiratory activity and of unconsciousness with apnea probably means that the entire brain undergoes the same rhythmic changes in capacity to function that are so evident in the respiratory center. The course of events is probably as follows: All nerve cells are depressed by anoxia; breathing stops, consciousness is lost, the vasomotor center loses its tone, and blood pressure falls. But the chemoreceptors can

still respond to the anoxemia and hypercapnia which result from the apnea; this, combined with the direct effect of the hypercapnia on the depressed but not paralyzed neurons of the center and the stimulus (reflex or direct) furnished by the fall in blood pressure, is enough to arouse the sluggish center and breathing begins. The blood is immediately oxygenated and the anoxic depression is quickly relieved: respiration improves, consciousness becomes less clouded, and blood pressure rises because the vasomotor center is now in better condition. But during the dyspnea the stimuli to chemoreceptors and center are reduced, breathing is depressed, and anoxia again supervenes.

In some patients, such as the one from whom the tracing shown in Fig. 258 was obtained, a prominent cause of the anoxia of the brain is spasm of cerebral blood vessels and breathing is made normal by drugs which dilate the vessels (theophylline, choline derivatives, nitrites). This is also the case in normal

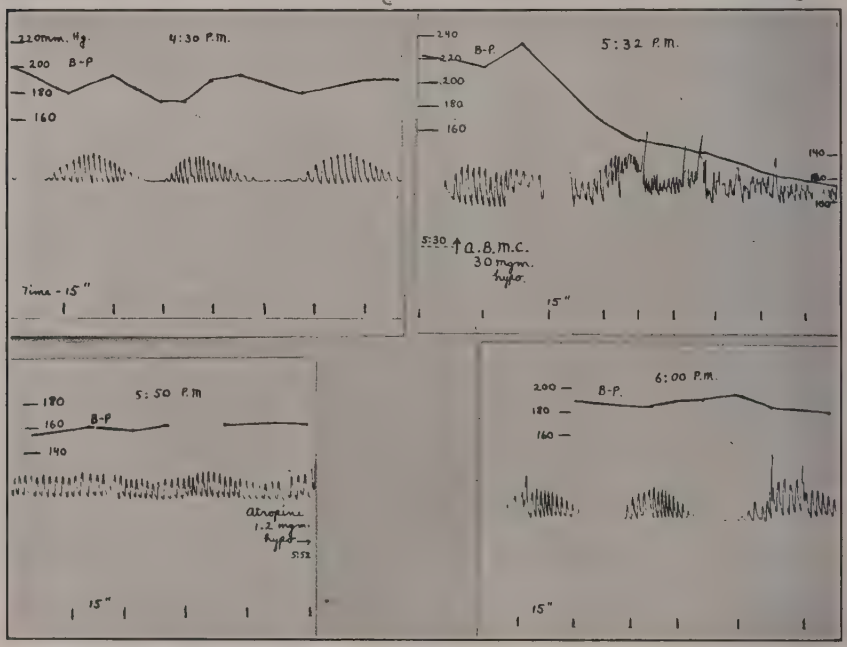

Fig. 258.—Cheyne-Stokes breathing in man.

Patient was seventy years of age, injured in trolley accident while under the influence of alcohol. No discernible damage to skull or brain. Record of respiration made by pneumograph; blood pressure read at frequent intervals by auscultatory method—systolic pressures drawn on record, calibration shown.

4:30 P.M.—control: patient completely unconscious during apneas, partly conscious while breathing. (He had been in this condition for more than twenty-four hours.)

5:30 P.M.—acetyl betamethylcholine—30 mg.—injected subcutaneously. Within a minute effects of drug began: face became flushed, there was profuse sweating, pulse became slower, and blood pressure fell from 220 to 118 (systolic) by 5:32. Patient became more nearly conscious than he had been for twenty-four hours: he tried to remove blood pressure cuff and struggled quite violently. Note absence of periodic breathing.

5:50 P.M.—patient asleep: no periodic breathing. Blood pressure has risen again as far as 155 mm.; skin still flushed and moist. At 5:52—atropine—1.2 mg. subcutaneously (to remove effects of the choline compound).

6:00 P.M.—atropine has acted: blood pressure has risen to 190 mm., skin pale. Periodic breathing has returned.

subjects who have developed Cheyne-Stokes breathing as a result of violent overventilation. In patients in whom cardiac disease is the cause oxygen inhalation quickly makes the breathing regular.

Cheyne-Stokes breathing due to high intracranial pressure resembles the form described above in that blood pressure typically rises during the dyspneic period and falls during the apnea (Fig. 257). There may be differences in the reactivity of the vasomotor and respiratory centers. If the vasomotor center is in better condition than the respiratory, blood pressure will rise before breathing begins because its cells are the first to respond to the rising stimuli, and the respiratory neurons are then helped by the improvement in their blood supply. In such cases respiration begins only after blood pressure has risen. But if the vasomotor neurons have suffered the same degree of damage as the respiratory, rise in blood pressure and onset of respiration coincide.

The ominous feature of Cheyne-Stokes breathing is that it indicates well-developed damage to the central nervous system by oxygen-lack. Breathing continues only because the respiratory neurons still have enough vitality left to respond to stimuli of abnormal strength, but they have lost their power to respond to slight changes and so to maintain normal breathing. The margin between damage severe enough to produce this condition and that sufficient to produce complete failure of breathing is probably very narrow.

(d) *Faulty Transport of the Respiratory Gases.*—This is responsible for the readiness with which dyspnea occurs in subjects whose alkali reserve is subnormal (acidosis, residence at high altitudes), or whose hemoglobin is subnormal in quantity (anemia) or quality (formation of compounds that do not yield oxygen with normal readiness, a result that can be brought about by carbon monoxide [carboxyhemoglobin—see page 694], and by substances which lead to the formation of methemoglobin or sulfhemoglobin). In many cases of this type dyspnea is not present under resting conditions because the existing circulatory and transport factors are adequate to supply the body's resting needs for a gas exchange and the chemoreceptors are not stimulated as long as the oxygen tension and pH in the arterial blood are normal (see page 592). Dyspnea does, however, occur with abnormal readiness when the metabolic needs of the body are increased.

The following generalizations, which are applicable to the phenomenon of dyspnea no matter how produced, may be of assistance to the physician in arriving at a decision as to what his attitude toward it should be:

1. Active contractions of the accessory inspiratory and the expiratory muscles account for a relatively excessive share of the total energy output of the body. This is indicated by Nielsen's work, to which allusion has been made (page 652). Since these muscle groups are necessarily involved in any dyspnea, it follows that dyspnea may be positively harmful as well as unpleasant to the patient, and it should be relieved whenever it is practicable to do so.

2. The subjective sensation of breathlessness appears always to depend upon persistence of the urge to breathe throughout the respiratory cycle, either because the combined nervous and chemical stimuli are overpoweringly strong or because the inhibito-inspiratory reflex influences are abnormally weak, or perhaps both. Direction of inquiry along these lines may lead to discovery of the responsible factor or factors and to proper decision as to how to remedy the situation.

3. There is a notable tendency to summation on the part of the various factors involved in dyspnea, and by far the commonest (and practically most important) instance of this is the well-known decreased tolerance to exercise. Present knowledge on this subject entitles us to conclude that there must be in such patients an abnormality which can stimulate the respiratory neurons either directly or reflexly but which is not yet severe enough to make itself manifest until the excitability of the center is increased by exercise. This factor may be one or more of those discussed above, and search along the proper lines may lead to its discovery in time to do something about it.

APNEA

Apnea simply means absence of breathing, but as generally used the term implies that the cessation is temporary. Prolonged apnea is simply respiratory failure and will be considered in the next section. Theoretically apnea might be produced by (1) reduction in the stimulus to the respiratory center, the latter having its normal ability to respond; (2) active inhibition of the discharge of impulses by the center, the stimulus being normal or augmented and the center likewise normal; (3) decrease in the ability of the center to react to the stimulus; (4) any combination of these. In experiments on anesthetized or decerebrate animals examples of the operation of each of these causes can be obtained without difficulty, and while the conditions are not actually normal, the underlying mechanisms are undoubtedly the same as in the normal animal.

Apnea in Experiments on Animals.—*Apnea due to reduction in the stimulus to the respiratory center* is seen when a reflex stimulus is suddenly withdrawn: the reduction in the chemical stimulus, which is produced by a hyperpnea of reflex origin, now makes itself manifest and breathing stops until the chemical stimulus is restored. A good example is the apnea which occurs when oxygen is breathed after inhalation of an indifferent gas such as nitrogen, hydrogen, or nitrous oxide (Fig. 259). A similar effect is produced by suddenly restoring the normal blood supply to the center during the stimulant stage of an acute cerebral anemia (Fig. 260). In this case the hyperpnea is due to accumulation of products of metabolism in the cells of the center, and the CO_2 tension of the blood is reduced; when the blood supply is restored, the diffusion of CO_2 takes place rapidly from the nerve cells to the blood, and apnea results until the CO_2 tension of the blood rises to normal again.*

Apnea due to active inhibition of the respiratory neurons can be produced by prolonging the inhibitory Hering-Breuer reflex, as by obstructing the trachea at the end of inspiration (Fig. 220, page 570). This causes relaxation of the inspiratory muscles and the resulting apnea lasts until the constantly rising CO_2 tension of the blood becomes stronger than the inhibitory nerve influence, for the latter diminishes only very slowly when the distention of the lungs remains constant (Adrian[2]).* A similar result is obtained when the carotid sinus pressure receptors are stimulated by a rise in intracarotid pressure (Fig. 226); the explanation is also similar, for the pressure receptors of the carotid sinuses, like the stretch receptors of the lungs, adapt very slowly (Bronk and Stella[31]) and the resumption of breathing is due to the overpowering effect of the increased chemical stimulus. In such cases the first respiratory effort is typically inspiratory, probably because the inspiratory neurons have a lower threshold than the expiratory to the CO_2 tension of the blood (page 556).

*Reflexes from the carotid sinuses play a part in the hyperpnea produced by occlusion of the carotid arteries and the apnea produced by release of the vessels, but they have little or nothing to do with the effects of simultaneous occlusion and release of the carotid and vertebral arteries, for denervation of the carotids does not modify the result. Adrenalin apnea (page 580) is also due in large part to reflexes from the circulation, but it can also be produced after section of the sinus and depressor nerves, in which case it is most probably due to decrease in the CO_2 tension in the respiratory neurons because of increased removal of the products of their own metabolism. As already mentioned (page 580) adrenalin apnea has little clinical importance because it is elicited only by intravenous injections of the drug and these produce such subjective disturbances in man that breathing is more likely to be stimulated than depressed.

Apnea due to decreased ability of the respiratory neurons to react to stimuli is produced by depressant drugs and poisons, especially when they are given so as to produce their effects very rapidly, as by intravenous injection. When so given most of these substances produce an immediate fall in blood pressure, before the central nervous effects are fully developed, and because of this (through reflexes from the carotid sinuses and aorta and through decreased removal of metabolic products from the center) breathing may be stimulated. By the time the central depressant effects have reached their maximum, the CO_2 tension of the blood may therefore be reduced by the initial hyperpnea and both influences combine to cause cessation of breathing. If the depression caused by the drug is not too severe breathing will begin

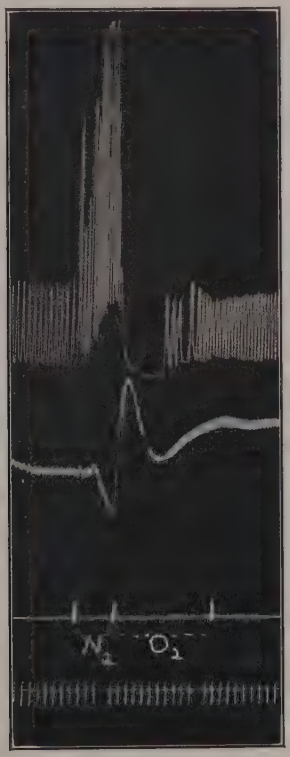

Fig. 259.

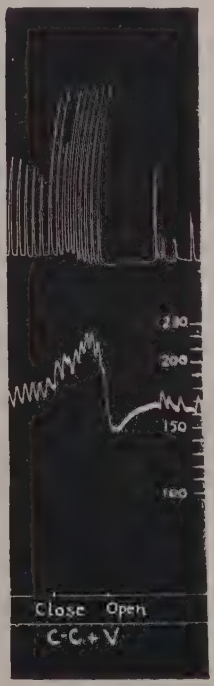

Fig. 260.

Fig. 259.—Apnea due to breathing oxygen after nitrogen. Cat—pentobarbital narcosis. Respiration recorded by plethysmograph, blood pressure by Hg manometer connected with femoral artery. Vagodepressor and sinus nerves intact. Nitrogen (undiluted) inhaled between first pair of signals. When dyspnea was at its height, nitrogen was removed and oxygen was supplied through a tracheal catheter until third signal mark. Time record shows five-second intervals.

Fig. 260.—Apnea due to restoration of blood supply of brain after a brief period of acute anemia. Dog: barbital narcosis; carotid sinuses denervated, vagodepressor nerves cut. Common carotid and vertebral arteries (C-C+V) closed and opened as indicated. Calibration at right applies to blood pressure record. (From Schmidt: Am. J. Physiol. **102**: 119, 1932.)

again when the CO_2 tension of the blood has risen sufficiently to arouse the now sluggish neurons to activity (Fig. 261). In all such cases the CO_2 tension of the blood rises above normal and the extent of the rise is a fair measure of the extent to which the reactivity of the neurons has been reduced.

Combinations of these are frequently encountered. The commonest and most important one is *simultaneous reduction in the stimulus and in the ability of the center to react to it.* This has just been mentioned in connection with intravenous injection of narcotic substances. It has also been mentioned (page 600) as a danger in inhalation anesthesia. A similar combination is encountered in *anoxemia* or in *oxygen-lack in the central neurons due to cerebral anemia no matter how produced,* for in anoxemia breathing is driven by reflexes and in cerebral anemia by accumulation of metabolic products in the cells of the center; the normal stimulus (blood CO_2) is reduced by the hyperpnea and the ability of the cells to react is simultaneously reduced by oxygen-lack within them. *Active inhibition of the cells of the center* becomes a serious factor only when it is combined with a diminution in the reactivity of the cells to chemical influences while their reactivity to afferent inhibitory influences is less reduced or actually exaggerated. This is the situation in animals anesthetized with chloralose, to a lesser extent after large doses of morphine; it also seems to be the case in some animals (and human subjects) under anesthesia by nitrous oxide and oxygen (Downs[48]).

Apnea in Man.*—All the types of apnea which we have just seen illustrated in experiments on anesthetized or decerebrate animals have their counterpart in man. The apnea due to reduction in the stimulus to the respiratory center is shown by overbreathing voluntarily for about two minutes, after which the subject has no desire to breathe again until the CO_2 tension of the blood has returned to normal. The apnea due to active inhibition

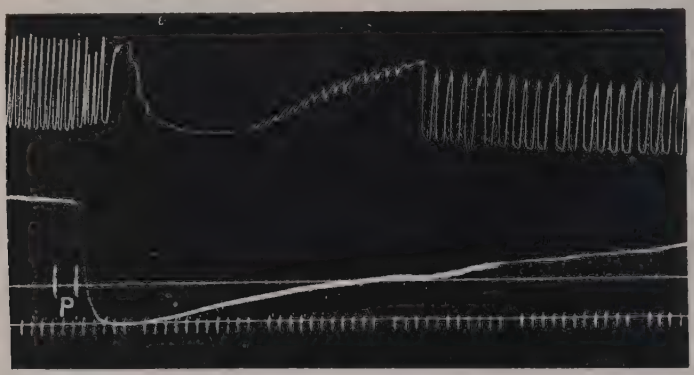

Fig. 261.—Apnea due to depression of the respiratory center by a depressant drug injected intravenously. Cat under light pentobarbital narcosis (corneal reflex active). At *P*, intravenous injection of 60 mg. of pentobarbital sodium.

of the respiratory neurons is illustrated by holding the breath voluntarily. Both of these types of apnea can be elicited more readily in normal man than in animals, not only because of voluntary cooperation, but also because the respiratory neurons are in a state of maximal reactivity to stimuli of all sorts. The apneas which depend on decreased reactivity of the center are also encountered in man—those produced by sudden absorption of a depressant drug as well as those due to oxygen-lack within the cells of the center. The latter frequently take the form of periodic respiration in man, which has already been considered (page 656).

RESPIRATORY FAILURE

Up to this point we have generally assumed that the sensitivity of the respiratory neurons is always the same and that differences in breathing are due to differences in the intensity of the chemical or nervous influences which act

*Until about five years ago it was generally believed that apnea normally exists in the fetus in utero and physiologists attempted to explain in various ways the beginning of respiration after birth. The work of Snyder and Rosenfeld, shows clearly that respiration is normally present in the fetus before birth; the first breath of air is simply a continuation of a process which has been going on for some time and which has been interrupted or impeded by the process of labor.

upon the center. In terms of the conception outlined on page 562, this means that the vegetative reactions of the neurons are being perfectly carried out and the capacity for generating and discharging motor impulses is maximal. It is under such circumstances that the respiratory center is so exceedingly sensitive to changes in the CO_2 tension of the blood. If all other factors are kept constant, the same maximal sensitivity to CO_2 is expressed in constancy of the CO_2 tension of the alveolar air.

These are ideal conditions for demonstrating the reactivity of the respiratory center, and it would be a mistake to apply the information so obtained to the abnormal situations which confront the physician; first some assurance should be had that the reactions of the respiratory center damaged by trauma, poisons, or disease are at least qualitatively like those of the normal. As a matter of fact they are not; the response of the center when it is depressed is not only quantitatively reduced but it is in some respects exactly opposite to the response under normal conditions. Since the physician's concern with the respiratory center is mainly limited to the abnormal, it is important to understand these differences.

The respiratory center is a relatively rugged structure. It has greater capacity to resist adverse conditions without surrendering its functions than any other part of the central nervous system excepting the closely related vasomotor center. This is seen in the familiar fact of general anesthesia, which is possible only because the respiratory and vasomotor neurons are able to continue at least a passable semblance of their normal activities when subjected to poisoning of a degree sufficient to paralyze the rest of the central nervous axis. It is also seen in the fact that respiratory and vasomotor functions can be restored even as long as 30 minutes after the circulation has ceased,[41] whereas the higher, more complexly organized parts of the central nervous system are irreparably damaged. The desire to breathe is perhaps the most irresistible of all the activities of the mammalian central nervous system. It is said[89] that man succumbs to immersion in water considerably sooner than necessary because he is unable to resist the impulse to breathe; consequently he draws water into his lungs and displaces the reserve supply of air in them long before he has utilized the oxygen which it contains. Recent studies[86, 95] of the factors responsible for the ability of diving mammals to remain submerged for relatively long periods of time make it probable that one of the most important of these factors is the ability to suppress the desire to breathe when it can only do harm to the organism. A similar ability is very seldom if ever sufficiently developed in normal man to permit us to regard inhibition of the normal human respiratory center as a possible cause of a dangerously long suspension of respiratory activity. Such a contingency can be expected only when the neurons are no longer normal.

It is obvious that the respiratory center cannot always have the same ability to react to stimuli. No matter how great its capacity for discharging impulses may be when its neurons are in a state of maximal reactivity, and no matter how much more resistant it is to adverse conditions than the rest of the central nervous system, its activity must eventually be decreased by the same agencies which decrease the activity of all living cells. This is indeed the case.

Severe asphyxia or anoxemia no matter how produced (pages 649 and 675) will eventually lead to cessation of breathing; respiration typically stops before the heart ceases to beat and the failure of the circulation is properly regarded as secondary to the failure of respiration. Among the commonest (and least hopeless) causes of this type of respiratory failure are inhalation of asphyxiating gases, drowning, practically total obstruction to the passage of air in and out of the lungs, and failure of the respiratory muscles (as in excessively high spinal anesthesia, transverse cord lesions, poliomyelitis, or extreme myasthenia). Respiratory and cardiac failure also ensue inevitably whenever the circulation fails because the flow of blood then becomes inadequate to supply enough oxygen to prevent anoxic derangement of the cells of the respiratory center and heart muscle; in such cases the restoration of these functions is impossible unless or until the circulation is restored.

The respiratory neurons are depressed by narcotic drugs such as alcohol, ether, chloroform, morphine, the barbiturates, and other depressants of the central nervous system. In

line with current trends we may attribute this depression in reactivity to an interference by the narcotic with the vegetative reactions of the neurons, thus leading to an increase in the interval required for them to prepare for another burst of activity (slowing in the rate of breathing) and to a decrease in the number of neurons involved in each burst (decrease in the depth) (see page 562). If the drugs are present in sufficient amounts, the nerve cells are rendered completely incapable of reacting to stimuli and respiration ceases. Usually the poisoning develops gradually as the concentration of the drug in the tissues increases and respiration becomes progressively slower and usually shallower before it fails entirely. Before the neurons are completely paralyzed, they can still react to increased stimuli, nervous or chemical, although much more sluggishly and much less strikingly than normally. Even after they have ceased functioning, they may still be aroused if the nervous or chemical stimuli which affect them are further increased. It is noteworthy, however, that the oxygen requirement of these neurons is reduced by narcosis and their susceptibility to the disorganizing effects of anoxia is correspondingly diminished—a relation of some importance in connection with resuscitation.

In addition to narcotic drugs, there are poisons which act primarily by interfering with tissue oxidations and which depress breathing because the respiratory neurons, like any other living cells, are depressed when their oxidative processes are deranged. The outstanding examples are carbon monoxide and cyanide. Monoxide acts by forming a stable compound with hemoglobin and thus preventing the liberation of oxygen from it (see page 692). Cyanide prevents the cells from utilizing oxygen (see page 714). Either may cause stimulation of breathing at first, but the serious aspect of their action is the respiratory depression which ensues.

Respiratory depression or failure is also a prominent danger in injury to the central nervous system. When the damage involves the medulla, through direct trauma or hemorrhage extending into it, the mechanism is quite evident, but the danger exists even when the medulla is not directly injured. This is because cerebrospinal pressure is likely to be elevated; when this pressure exceeds that in the cerebral capillaries the flow of blood in the latter becomes impossible and the entire brain suffers from acute anemia (see page 655). Cerebrospinal pressure is raised in inflammatory disease and tumors of the central nervous system and in certain toxemias, such as uremia and eclampsia, which do not involve the central nervous system directly. In narcotic poisoning the cerebrospinal pressure is usually elevated also —a fact which may be of importance in determining the outcome, for in such cases the vasomotor center is much less reactive than normally and therefore incapable of raising the blood pressure as it should.

Respiration is also depressed by anemia of the brain produced by mechanisms other than increased cerebrospinal pressure. This is apt to be forgotten because acute cerebral anemia produces a marked stimulation of breathing if the center is normal (page 653). This stimulation is transitory; if the anemia continues, the respiratory stimulant response is not maintained, but gives way either to a return to normal breathing or to progressive depression followed by failure. Such a situation is encountered whenever the blood pressure is markedly reduced, as in hemorrhage or shock. A reduction in cerebral blood flow that would be unimportant under ordinary circumstances may cause respiratory failure if produced when the supply of oxygen to the brain is deficient because of a shortage either in the oxygen content of the blood or in the amount of blood flowing through the organ. This probably accounts for permanent respiratory failure on stimulation of the carotid sinus pressoreceptors during nitrous oxide anesthesia (Downs[48]) and perhaps also for the tendency of patients with high cerebrospinal pressures to cease breathing when relatively slight reductions in blood pressure are brought about.

Respiratory failure may occasionally follow the sudden relief of a sub-total obstruction of the respiratory tract when performed during the dyspneic stage, as by intubation of the larynx, or by insertion of a tracheotomy tube in a patient with laryngeal obstruction.[117] The mechanisms involved here are as yet very imperfectly understood. The explanation that seems most probable to the writer is that the central neurons had previously suffered so much damage from prolonged exposure to anoxemia that they could be kept active only by a powerful chemoreceptor drive (also due to anoxemia), and when the latter is suddenly eliminated by the first free breath or two after the operation, the neurons cease functioning. Perhaps the situation here is essentially the same as that described by Courville[42] in connection with delayed deaths or permanent neurologic sequelae following

nitrous oxide anesthesia, viz., more or less extensive degenerative lesions in the brain substance itself—a situation that can be prevented but not remedied.

A special form of respiratory failure is that encountered in newborn infants. This will be dealt with separately (page 672).

These are circumstances under which depression or failure of respiration is likely to cause death and improvement of respiration may lead to recovery. This is especially true in poisoning by depressant drugs, for these do not directly damage the tissues. There is one common factor in all of the conditions in which respiratory failure is likely to occur, and that is oxygen-lack in the cells of the center. In narcotic poisoning it is produced by the decreased pulmonary ventila-

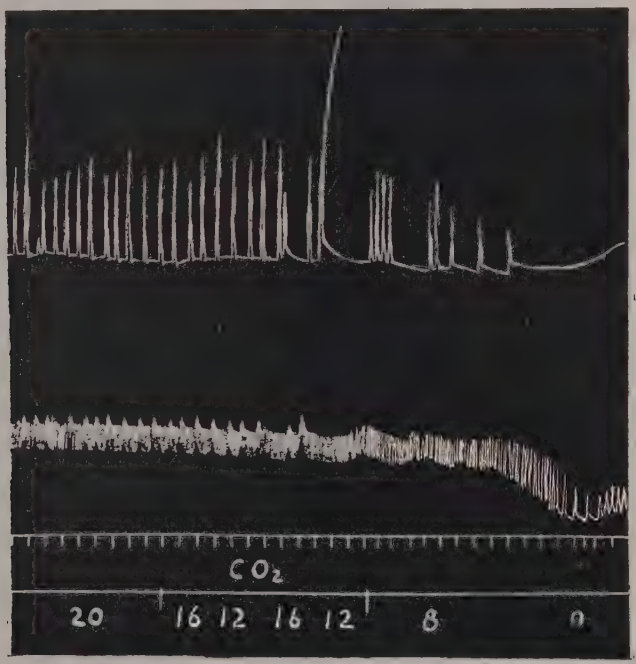

Fig. 262.—Respiratory failure following inhalation of CO_2. Dog: urethane and morphine. CO_2—6 per cent in air—inhaled for one minute; the numbers indicate rate of respiration per minute. Upper record, respiration; lower record, arterial pressure. (From Schmidt: Am. J. Physiol. 84: 202, 1928.)

tion consequent upon the narcotic depression of the center; by an interference by the narcotics with cell oxidations including those in the respiratory neurons; by depression of the vasomotor center, an effect which all these substances are likely to have in toxic dosage; and by the raised cerebrospinal pressure which is also commonly produced by them when the dosage is dangerously large. In poisoning by carbon monoxide or cyanide the oxygen shortage is begun by deficient supply of oxygen by the blood (monoxide) or by deficient utilization of oxygen by the cells of the center (cyanide), but as respiration becomes depressed, insufficient pulmonary ventilation adds another factor leading to oxygen-

lack; in addition, cerebrospinal pressure is raised in monoxide poisoning. In cases of subacute cerebral anemia, whether due to high intracranial pressure or to low systemic blood pressure, the chief factor is an insufficient supply of blood to the center: it does not get enough food material or oxygen and its waste products accumulate within it.

In all these cases the respiratory center suffers from shortage of oxygen and since this can be remedied promptly while relief of direct depression of the center by trauma or poisoning requires time, it is important to recognize the dangers of oxygen-lack and to remove them as far as possible. Shortage of oxygen is not narcotic in the usual sense but rather disorganizes the internal economy of the cells. It reduces specialized functions because it interferes with the vegetative reactions upon which the specialized functions are based (p. 519).

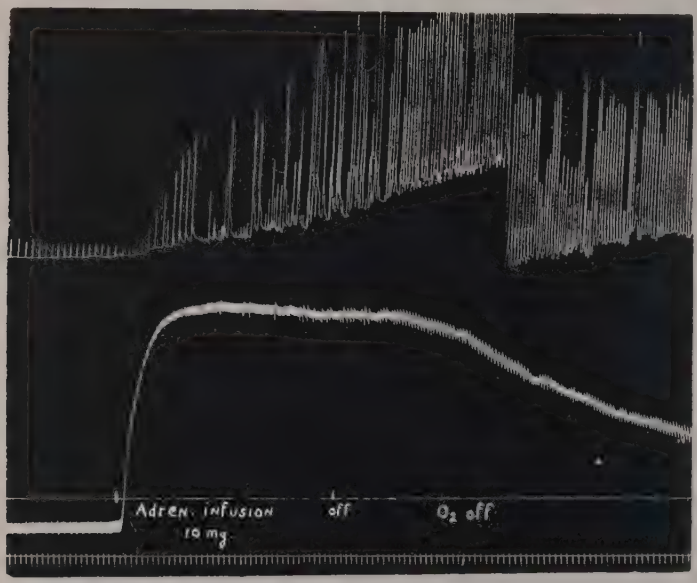

Fig. 263.—Respiratory stimulation by adrenalin. Dog: urethane and morphine. Upper record respiration; lower, arterial blood pressure. Oxygen by catheter in trachea for five minutes before this record was made—discontinued at "O_2 off."

This sort of change is added to that which had caused the initial depression of respiration and a vicious circle is set up: oxygen-lack in the neurons leads to further respiratory depression, this leads to further diminution in the amount of oxygen taken into the blood, and this causes still further depression of the center. The depression originally caused by trauma or poison is thus intensified.

Under such circumstances the behavior of the respiratory center differs both quantitatively and qualitatively from the normal. Quantitatively, the response to chemical stimuli is greatly reduced, as one would expect, since breathing is depressed although the CO_2 tension of the blood is abnormally high; CO_2 inhalation may elicit some stimulant response but this is apt to be slight at best, and it may be entirely lacking. Afferent stimuli, particularly those arising from the chemoreceptors, are relatively more important than they are normally, and breathing may be maintained only because anoxemia is present, the center having lost practi-

cally all of its normal capacity for responding to changes in carbon dioxide content in its cells, while the receptors of the carotid and aortic bodies continue to function. Consequently, substances which normally excite these receptors (such as lobeline and cyanide) are usually more effective than CO_2 inhalation in stimulating breathing when it is about to fail or has failed, but the effects are much less intense than they normally are and when breathing has ceased these agents may be entirely ineffective. Drugs which arouse nerve cells to greater activity (strychnine, caffeine, atropine, camphor, picrotoxin, metrazol, coramine) produce progressively less respiratory stimulation as the depression becomes more profound, and when death is imminent, because of insufficient respiration, they are apt to be entirely ineffective.

As for *qualitative* differences from normal, the respiratory center that has been subjected to oxygen-lack for some time may be depressed by agents which normally stimulate breathing and it may be stimulated by agents which normally would depress it. Thus CO_2 inhalation, or any of the drugs which stimulate nerve cells, may cause brief stimulation followed by depression or failure of breathing (Fig. 262), while adrenalin, which normally causes apnea, is one of the most effective agents in restoring breathing after it has failed (Fig. 263).

The explanation of this paradox is probably as follows: when the central neurons are laboring under a supply of oxygen barely sufficient to meet their needs, a stimulation of their activity entails an increased call for oxygen which cannot be furnished, and a subacute oxygen shortage is thus transformed into an acute one—hence the transitory stimulation followed by depression. On the other hand, the increase in blood pressure produced by adrenalin greatly increases the blood supply of the brain; normally this means inhibition of respiration through stimulation of the pressure receptors of the carotid sinus and aortic systems as well as removal of stimulant material produced in the center by its own metabolism, but now the increased blood supply of the center increases the amount of oxygen available to it and at the same time washes depressant material (accumulated metabolic products, narcotic drugs if present) out of it; thus its capacity for discharging impulses is increased.

From these considerations it follows that respiratory failure, for all practical purposes, may be regarded as synonymous with severe anoxia in the neurons of the respiratory center. In most cases anoxia plays a prominent part in bringing about the initial failure by disorganizing these cells and diminishing their capacity to respond to stimuli, but even if this were not the case anoxia would inevitably result as soon as the breathing became insufficient. This conclusion is of the utmost importance when it comes to restoring breathing after it has failed, which is the subject next to be considered.

RESUSCITATION

Having considered the conditions under which respiratory failure may occur and the underlying derangements in the regulating system, we come to an inquiry into the measures that should be employed to rectify these disturbances and thus to restore respiratory activity. If we are correct in our conclusion that disorganization of the central neurons by anoxia is a common factor of dominant importance in all cases of respiratory failure, several deductions of importance with regard to the physician's attitude toward these conditions may at once be drawn: (1) *Prevention is greatly to be preferred to cure,* for anoxia is prone to set vicious circles into operation and to cause irreversible changes in the central nervous system (Chapter XLV); the margin between complete reversibility (i.e., full recovery) and partial (i.e., permanent neurological sequelae) or complete irreversibility (i.e., failure to reinstate any vital activity) must be narrow at best, variable, and unpredictable. (2) *Speed is essential,* for the ability of the cortical cells concerned with the higher cerebral functions to withstand the disintegrative influence of anoxia is much less than that of the medullary neurons, and even though it is possible to restore respiratory activity as long as thirty minutes after the heart has ceased to beat[41] the cerebral functions of such an individual are not likely to return. (3) *No good will be accomplished by inducing greater activity in the central neurons unless their functional state is improved at the same time;* on the contrary, as we have just seen, attempts at resuscitation that involve increased activity by the neurons when their oxygen supply is barely adequate may turn a subacute oxygen shortage into an acute one and thus lead to complete failure. (4) *Successful resuscitation after respiration has failed must always depend upon two things:* (a) *improvement in the capacity of the neurons of the center for carrying on their function, which means rectification of the disorganizing effects of anoxia, removal of depressant poisons if present and avoidance of reduction in the carbon dioxide tension of the blood to a level below that required to maintain activity*

in the respiratory neurons (page 672); (b) *prevention of further (probably irretrievable) damage by anoxia during (or because of) the attempt at restoration.*

If these general principles are valid (as I believe them to be), it follows that the physician's attention in all cases in which resuscitation is attempted should be focused upon the institution and maintenance of an adequate supply of oxygen to the brain and the heart, for these are not only the parts of the body upon which resuscitation most directly depends but they are also the most vulnerable of all body tissues to the disorganizing effects of oxygen lack. If an abundant supply of oxygen is provided for these structures recovery will take care of itself; if it is not recovery is manifestly impossible.

From this viewpoint the appropriate procedures are as follows:

(1) *Provision must first be made for securing an adequate oxygenation of the blood in the lungs* and the first step is to see that the air-bearing system is freed of obstructions by appropriate measures (removal of water in drowning, in other cases by intubation of the larynx, tracheotomy, removal of foreign bodies, etc.). Then oxygen (if available) should be administered (preferably with the addition of about 5 per cent CO_2—see below), either through a suitable inhalator or by means of a catheter passed down the trachea to its

Fig. 264.—Resuscitation by oxygen administered by tracheal catheter. Cat: pentobarbital narcosis; at P—pentobarbital sodium—130 mg.—injected intravenously; oxygen administered by catheter between signals at "Oxygen." Note restoration of blood pressure and respiration by this procedure, indicating that oxygen-lack (produced by the initial cessation of breathing) was responsible for much of the total depression.

bifurcation (Figs. 264 and 265). Artificial respiration may also be applied, but the temptation to overdo this (which is great) should be resisted if oxygen is being supplied by the tracheal catheter, for the alveolar gas pressure may then be raised sufficiently to interfere with the pulmonary circulation. Once the oxygenation of blood in the lungs has been cared for, if the heart is still beating there is no danger of immediate death and the remaining measures can be applied deliberately. If the heart is no longer beating, immediate steps (such as intracardiac injection of adrenalin plus cardiac massage) must be taken to start it; this should not be done before oxygenation of the blood in the lungs has been cared for because, if it is, the increased cardiac effort resulting from adrenalin (if effective) will probably lead to rapid and irretrievable cardiac failure unless the blood in the coronary arteries is well oxygenated.

(2) *Attention should now be directed to the circulation,* for it is by this, and this alone, that oxygen is carried to the brain and depressant poisons (metabolic products or foreign chemicals) are removed from it. If blood pressure is low, steps should be taken to raise it (by transfusion of blood or by pressor drugs such as adrenalin, ephedrine, benzedrine, paredrine, etc., see Figs. 263 and 266). If the pressure of the cerebrospinal fluid is high, it may

be lowered by the intravenous administration of hypertonic fluids (sucrose or d-sorbitol in 50 per cent solution, or concentrated "lyophile" serum*); since anoxia apparently produces a distinct increase in the permeability of cerebral blood vessels, the administration of large amounts of fluid in such cases is undesirable because of the likelihood of further cerebral edema and a further rise in cerebrospinal pressure; the advisability of lowering this pressure by removal of fluid in the lumbar or cisternal space calls for clinical judgment; the physician must remember that if the cerebrospinal pressure is as high as or higher than that in the cerebral capillaries (which must be at least a little lower than that in the major arteries) resuscitation is impossible. The observer must be prepared for a rapid and steady decline of blood pressure if adrenalin has been used to start the heart or to raise the blood pressure, for this drug is rapidly destroyed in the body and its effects are correspondingly brief. Furthermore, oxygen inhalation or insufflation may cause a fall in blood pressure

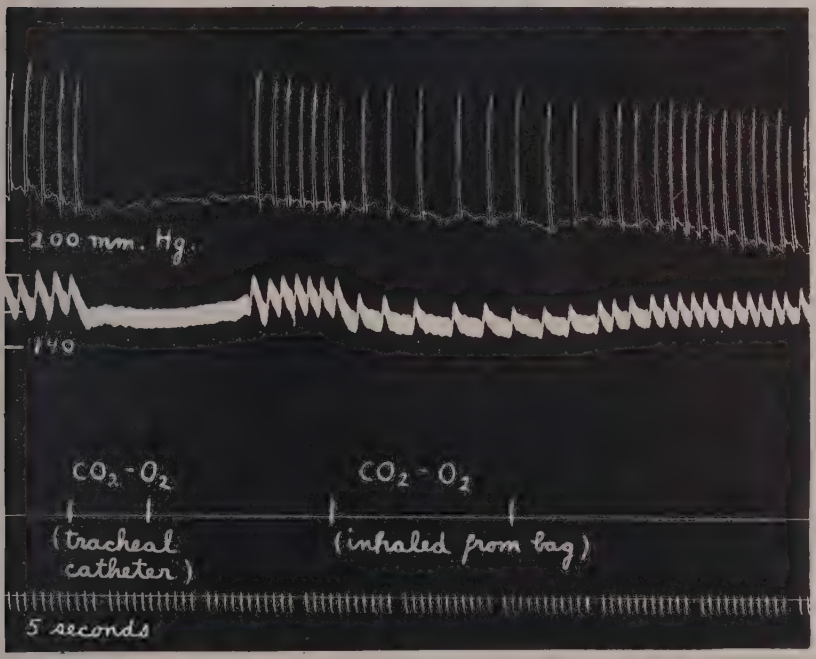

Fig. 265.—Depression or cessation of respiration as a result of inhalation of CO_2 and O_2.

Dog: anesthesia by urethane and chloralose. Vagodepressor and sinus nerves intact. Upper record—pneumogram. Femoral blood pressure—mercury manometer, calibration shown.

CO_2—10 per cent in oxygen—administered first by catheter whose tip lay just above bifurcation of trachea, then by inhalation from a bag attached to inspiratory valve of tracheal cannula.

Depression of breathing was probably due to removal of anoxemia.

in certain instances, probably because impulses aroused in the chemoreceptors by anoxemia have been instrumental in maintaining vasomotor activity (the so-called MacDowall reflex—Comroe[39]). Care should be taken lest the preoccupation of the observer with other matters

*These are better than glucose because the latter, being so much more readily diffusible through living membranes, is apt to leave the circulation and enter the brain where it will attract more fluid and may cause a rise in intracranial pressure to a level higher than the initial one. The saccharides have the advantage, in cases of narcotic poisoning, of causing considerable diuresis, which aids in the removal of the toxic agent from the body after it has been detached from the brain cells and before it can recombine with them. Sucrose has recently[100] been accused of causing severe damage to the kidney, and perhaps sorbitol, which seems above suspicion in this regard, deserves preference.

lead him to neglect these phenomena until the circulation has become insufficient. The patient's body temperature should also be watched and steps taken to see that it does not fall, as it may; in poisoning by barbiturates, however, fever is not unusual.

(3) *Steps may now be taken to remove the cause of the original depression.* If this was largely or wholly due to the disorganizing effects of anoxia, nothing need (or can) be done other than to insure an adequate oxygenation of the blood in the lungs, an adequate flow of blood in the cerebral and coronary systems (both dependent directly on the level of systolic blood pressure), and an adequate content of carbon dioxide in the arterial blood; since carbon dioxide is also a most effective dilator of cerebral vessels, an adequate patency of these is thus insured without the risk of additional cerebral edema or fall in systemic blood pressure that would attend the use of vasodilator drugs other than CO_2. The use of stimulant drugs, in hopes of hastening the return of spontaneous breathing, is probably advisable only if depressant drugs were a factor in the original depression. When the depression was due to a drug or poison, specific measures aimed at getting rid of the toxic agent will be indicated, but these will vary according to the substance to be removed: in poisoning by carbon monoxide, inhalation of oxygen plus carbon dioxide is effective (page 694); in cyanide poisoning the administration of nitrites and sodium thiosulfate leads to the

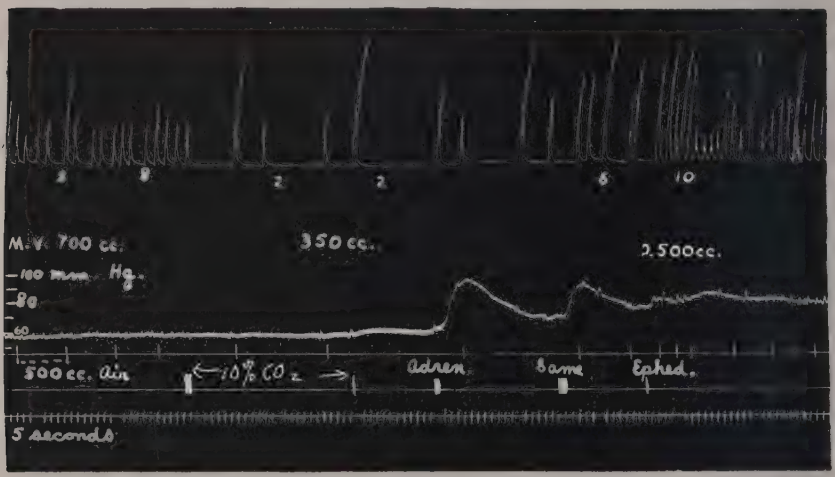

Fig. 266.—Further depression of a depressed respiratory center by inhalation of CO_2 in O_2

Dog: anesthesia by urethane and chloralose; 100 mg. of morphine sulfate injected intravenously ten minutes previously. Vagodepressor and sinus nerves intact. Records (from above down): respiratory movements (pneumogram), rate indicated; femoral blood pressure—mercury manometer, zero at time tracing, calibration shown; volume of expired air, each signal mark repesenting 500 c.c. (ml.), minute volume (*M-V*) shown under figures for respiratory rate; signal; time.

CO_2—10 per cent in oxygen—administered from bag through inspiratory valve attached to tracheal cannula.

Adren.—adrenalin—0.5 mg.—intravenously.

Ephed.—ephedrine hydrochloride—10 mg.—intravenously.

Depression of breathing followed two breaths of the CO_2–O_2 mixture and was probably due to the narcotic effects of CO_2. Note improvement following adrenalin and ephedrine.

formation of cyanhemoglobin and the transformation of the cyanide into relatively harmless thiocyanate; in poisoning by narcotics, or other agents taken by mouth, lavage of the stomach and the administration of activated charcoal (to adsorb the remaining poison) and of dilute sodium (not magnesium, which is itself a narcotic) sulfate or phosphate, to hasten this along the bowel, are measures to be employed. In narcotic poisoning it is also to be remembered that removal of the poison from the brain must be accomplished by the circulation, and, other things being equal, the better the circulation the more rapid the recovery.

The question of *respiratory stimulant (analeptic) drugs* has intentionally been put last in this discussion because (in my opinion) their value is considerably smaller than their potentialities for doing harm. Our inquiry into the derangements that must be remedied or compensated if resuscitation is to be successful should have disclosed the futility of the search for a *therapia magna*—a specific, multivalent remedy—for all forms of respiratory failure. By this time it should be clear that there is need for rapid, effective action whenever anoxia is at work if irretrievable damage is to be avoided, and the precious time used in administering one or more of the analeptic drugs (strychnine, camphor, atropine, caffeine, picrotoxin, metrazol, coramine, hexeton, etc.), and in waiting for their effects to appear, may be very badly spent. It would seem to be better on the whole for the physician to forget all about these drugs under such circumstances and to concentrate his attention on measures that can be counted upon to break the vicious circle of anoxia, as encountered when respiration has become inadequate. These measures have already been considered (page 668).* Most of the drugs by which respiratory failure is apt to be produced have relatively prolonged effects and most of them are excreted unchanged from the body to a greater or lesser extent. Even if the analeptic succeeds in dislodging such a drug from combination with the neurons the depressant may recombine as soon as the effects of the analeptic wear away. Thus it would be unusual for any analeptic (or combination of analeptics), unsupported by other measures, to furnish an adequate treatment in narcotic poisoning sufficiently severe for the treatment to determine the outcome, even when the depression is almost purely a phenomenon of narcotic poisoning with a minimum of complication by anoxic derangement of the neurons. Since the narcotic depression is a completely reversible process, recovery should result just as surely, if perhaps a little more slowly, without the analeptic, simply from maintaining a good oxygenation of the blood in the lungs and a good circulation through the brain and heart. The latter, in my opinion, is the preferable procedure because of greater certainty in terminating and obviating anoxia and smaller risk of doing harm, either through self-deception or through aggravation of the anoxia. The depression due to anoxia cannot be favorably influenced by an analeptic and may be made worse.†

From the standpoint of effectiveness in eliciting respiratory movements the drugs which stimulate the chemoreceptors (lobeline and cyanide are the only ones that have been used therapeutically) are undoubtedly superior to the analeptics or convulsants. This is probably because the respiratory neurons, whenever resuscitation is needed, have been so deranged that they have lost the ability to respond to changes in the chemical composition of their environment and this derangement cannot readily be rectified by a convulsant drug; at the same time they may still be able to respond to the (presumably) more violent reflex disturbance set up in their vicinity by maximal stimulation of the chemoreceptors (see page 592). It should be noted, however, that the strong chemoreceptor stimulants are (as far as is now known) depressant to nerve cell activity, and reflex stimulation of respiration by them is therefore accomplished at the risk of further depression of the central neurons, not only because an existing derangement is apt to be intensified by increased activity thus demanded of them under adverse circumstances, but also because the agent responsible for the increased activity may directly add to the derangement. The place of such stimulants in the picture of resuscitation would seem to be to serve as tests of the possibility of resuscitation when respiration does not begin even though the oxygen and carbon dioxide

*The analeptics probably have a real place in the treatment of very acute overdosage with narcotic drugs; perhaps the best possible place for them is found in the recent practice of continuous intravenous infusion of a rapidly acting barbiturate such as pentothal. Under such circumstances the excessive depression occurs under the eyes of the anesthetist, is immediately recognized, and can promptly be remedied by intravenous injection of an analeptic (picrotoxin seems most successful). The action here is probably a displacement of the narcotic from its anchorage in the nerve cells by means of the analeptic, and a component of anoxic depression is minimal, partly because this type of anesthetic procedure is (it is to be hoped) carried out only by skilled individuals provided with all the necessary equipment, partly because the demand of the brain cells for oxygen is reduced by the depressant drug as the narcosis deepens. It should be noted, however, that the only narcotics that can be used in this way without undue risk have very brief effects; they are not likely to recombine with nerve cells after they have been detached and the original depression therefore should not return subsequently. A similarly ideal set of indications for an analeptic is probably not to be expected under any other circumstances: the onset of respiratory failure under the eyes of a specially skilled attendant who is looking for it and is prepared to take appropriate action instantly without permitting anoxia to supervene, the depression brought about by a drug the effects of which are very brief—each of these is distinctly unusual and seldom encountered, and the coincidence is probably unique. Narcotic poisonings as a rule develop gradually and by the time breathing has failed circulatory depression and anoxemia will have existed for some time.

†The cause of death in many cases of barbiturate poisoning in man is not respiratory depression but intercurrent pulmonary infection. This is another reason for concluding that the value of analeptics in such conditions is very limited if existent.

content of the arterial blood and the blood supply of the brain and heart have been cared for. These drugs cannot safely be used to maintain breathing under such circumstances, since the margin between reflex stimulation and direct central depression is entirely uncertain; they certainly cannot be used to replace the other procedures and they lack the property (possessed by the analeptics) of displacing narcotic drugs from combination with nerve cells.

THE EFFECTS OF INHALATION OF CO_2 IN OXYGEN WHEN THE RESPIRATORY CENTER IS SEVERELY DEPRESSED

These merit special attention because inhalation of CO_2 has come into widespread use for resuscitation. The general belief is that it is the most effective means of stimulating a depressed or paralyzed respiratory center and that even if it does no good it can do no harm. We must remember, however, that CO_2 is not a general stimulant to nerve cell activity, but is a depressant (narcotic) in the same sense, and probably through the same mechanisms, as alcohol or ether (Winterstein[151]). Its stimulant effects upon the medullary centers are quite unusual, and must be regarded as the result of a highly specialized function of these cells. But specialized functions are readily deranged, and this one certainly is deranged when respiration is badly depressed or ceases in the face of an abnormally high CO_2 tension in the blood, as is usually the case. The narcotic effect of CO_2, on the contrary, can be exerted upon any living cell, and it follows that an increase in the CO_2 tension of the blood can further depress the cells of the center when they have lost their specialized property of being stimulated by it. This is probably the explanation for depression of breathing, with little or no stimulation, after an animal whose breathing has been depressed by narcotics has taken a few breaths of air containing CO_2 (Fig. 266).

Another way in which CO_2 can cause respiratory depression in animals poisoned by narcotics is by stimulating the center when its oxygen supply is subnormal because of anoxemia, low blood pressure, or high cerebrospinal pressure (Fig. 262). This type of result, as we have already seen (page 666), may be obtained by any agent which increases the activity of the center (and therefore its need for oxygen) when its oxygen supply was barely sufficient for its needs before it was stimulated. The depression produced in this way is serious because it is due to a derangement of the vegetative functions of the cells and this is less readily reversible than a narcotic depression.

Still another way in which CO_2 in oxygen can cause cessation of breathing is by removing anoxemia (by virtue of the oxygen of the mixture) when afferent impulses aroused by anoxemia were the principal factor by which breathing was being maintained, as may be the case in profound narcotic depression (Fig. 265). If the gas mixture is supplied through a tracheal catheter, breathing may remain absent as long as the current continues to flow, but if it is inhaled in the usual manner, anoxemia soon reappears and breathing is resumed, though at a much slower rate than before (Fig. 265). An effect of this sort is not serious, and CO_2 cannot be said to be depressant in such a case; it is, however, without evident stimulant properties.

These observations indicate that the proper place of CO_2 in the treatment of severe respiratory depression is not to stimulate the center directly (in which it may be entirely unsuccessful, or if successful, dangerous), but to prevent reduction in the chemical stimulus of the blood by measures intended to combat anoxemia. The addition of 5 to 10 per cent CO_2 to the oxygen used for intratracheal insufflation, or inhalation of the mixture while artificial respiration is being employed, will prevent reduction in the CO_2 tension of the blood below the level at which the cells of the center are active and thus will assist in restoration of breathing when the deleterious influences of oxygen-lack and depressant agent are rectified by the procedures mentioned on page 668. In poisoning by carbon monoxide the addition of CO_2 to the inhaled oxygen has a special importance because it helps to release CO from its combination with hemoglobin. In all cases of severe respiratory depression, however, the all-important procedure is the administration of adequate amounts of oxygen; the addition of CO_2 is helpful in the sense noted above, but CO_2 should not be regarded as the life-saving agent.

ASPHYXIA NEONATORUM

Newborn infants who refuse to breathe spontaneously have always furnished a problem for the physician, but there seems little doubt that the condition is now being encountered more frequently than ever before. For this the use of nonvolatile narcotic drugs in dosage

large enough to produce unconsciousness, or at least amnesia, in the mother is undoubtedly responsible. The respiratory functions of the fetus have been studied intensively in recent years, and it is now possible to come closer to an understanding of fetal asphyxia than had previously been the case. The reader who is especially interested in this subject is referred to recent publications by Barcroft[117] and Windle.[165, 166] Until very recently it seemed probable that the fetus in utero normally makes respiratory movements by which amniotic fluid is drawn into the unexpanded fetal lungs, but the burden of evidence now is against this belief; respiratory movements in utero and aspiration of amniotic contents can occur, but only if the fetus is asphyxiated. Respiration of the fetus apparently can be stimulated either by increase in CO_2 tension or decrease in oxygen tension in the placental circulation, but the sensitivity to both stimuli is at best much less than in the adult and it is greatly reduced by narcotic drugs.

When these findings are considered in relation to existing information concerning the peculiarities of the circulation and the respiratory gas exchange in the fetus (Barcroft[116]) it becomes highly probable that asphyxia neonatorum is simply an extreme instance of respiratory failure due to oxygen-lack in the center. It is known that the arterial blood pressure of the fetus is low (less than 80 mm. in the sheep at term, and this animal is born in a much more developed state than man[115]); it is also known that the blood in the umbilical vein (which is the arterial blood of the fetal gas exchange) is only about 60 per cent saturated with oxygen while the normal human fetus is still *in utero*[51a]; when we remember that the arterial and venous circulations communicate by several channels in the fetus, it is evident that the blood which supplies the brain must contain considerably less oxygen than this, and it is probable that the actual figure is approximately half the 60 per cent saturation found in the umbilical vein. For these reasons alone we may conclude that the brain of the normal fetus must have been exposed to anoxia of high degree for some time before birth. In the process of birth the fetal anoxia is aggravated by the uterine contractions, which interfere with the gas exchange in the placenta; any direct interference with the circulation in the umbilical cord by pressing, pulling, or kinking would, of course, be an additional factor working in the same direction.

Table XXIII shows the average figures for the pH and oxygen and CO_2 content of blood collected from the umbilical veins of newborn human infants (Eastman[51c]). There are three groups of observations: the first comprises 7 infants delivered rapidly and spontaneously without anesthesia of the mother and one delivered by cesarean section under local anesthesia, this group representing the situation in an uncomplicated normal delivery without fetal asphyxia; the second group consists of 4 babies delivered by forceps with the mother under anesthesia by gas-oxygen-ether, representing moderate but not severe fetal asphyxia (all the babies of this group were crying actively within a minute after birth); the third shows the average of the results in 6 infants born in a state of severe asphyxia, to which three of them succumbed.

TABLE XXIII

AVERAGE GAS CONTENT AND PH OF BLOOD FROM THE UMBILICAL VEINS OF HUMAN FETUSES AT BIRTH (AFTER EASTMAN[51c])

	PH	CO_2 CONTENT (VOLS. PER CENT)	CO_2 TENSION (MM. HG)	O_2 CONTENT (VOLS. PER CENT)	O_2* SATURATION PER CENT
Normal delivery	7.36	45.9	35.5	10.6	51
Forceps delivery (recovery in all)	7.20	40.1	44.8	7.3	35.1
Severe asphyxia (fatal in 3 of 6)	7.04	37.5	61.6	1.3	6.3

*Calculated from an average oxygen capacity of 20.8 vols. per cent in fetal blood as given by Eastman.[51a]

From these results it is quite evident that the newborn child suffering from asphyxia has no deficiency of chemical stimulus to instigate respiratory activity, for the most nearly arterial blood in its body has a markedly reduced pH and a CO_2 tension nearly double that of the child in which breathing begins spontaneously; the lower CO_2 content is attributable to accumulation of lactic acid which Eastman[51b] has shown to occur in the asphyxiated infant—an uncompensated alkali deficit (page 646). The asphyxiated infant is suffering

from oxygen-lack of a degree seldom encountered in human beings, and the reason it does not breathe is that its respiratory neurons are so badly deranged by anoxia as to be unable to discharge impulses even though the stimuli to which they are subjected would ordinarily arouse them to maximal activity. Its inordinate sensitivity to depressant drugs is probably due to anoxia. Normally anoxemia stimulates breathing reflexly, but Snyder and Rosenfeld[151] believe that the carotid body mechanism has not yet begun to function at birth; this is in accord with the work of Clark[28] who found that the pressure reflexes from the aorta and carotid sinuses first appear four to six days after birth in dogs. The studies of Wilson and his collaborators[164] indicate that this is not true of the chemoreceptors of man, for they found the respiration of newborn infants to be strongly stimulated by lobeline—a drug which, as far as is now known, owes all of its stimulant effects on respiration to reflexes aroused by it in the carotid and aortic bodies. There is another and (to the writer) more attractive explanation for the failure of anoxemia to stimulate respiration in the fetus. We must remember that the fetus has been exposed to anoxia for a considerable time before birth, and though the consequences are not as drastic as they will be in the mature organism, this is only because the oxygen requirements of the fetus are lower than they ever can be when independent existence begins; furthermore, fetal anoxia is greatly exaggerated during birth; finally, the fetus has no stores of oxygen in the lungs to be drawn upon when the supply of oxygen from the maternal circulation is impeded during labor. If we correlate these with the additional fact that acute anoxia is undoubtedly able to depress neurons in general, including those of the respiratory center, we may conclude that the failure of acute anoxemia or asphyxia to stimulate respiration in the asphyxiated fetus is due to anoxic derangement of the neurons and not to absence of excitatory impulses from the chemoreceptors; further anoxia simply makes the neurons incapable of responding to any stimuli. The point has importance in connection with the treatment of this condition.

The *treatment* of asphyxia neonatorum, in the light of these studies, is clearly to be aimed at combating anoxemia, as Eastman pointed out some years ago. The administration of oxygen (preferably by tracheal catheter, with a pressure not higher than 12 mm. Hg[164]) is the first consideration; addition of 5 per cent CO_2 is desirable, not in the hope of stimulating the center (which CO_2 cannot do until the anoxic derangement is removed) but to obviate reduction in the CO_2 tension of the blood below the level at which the respiratory neurons are active. According to Wilson et al.,[164] lobeline injected into the umbilical vein before the cord is cut will immediately start respiration in a large proportion of these infants and thus lead to the greatly desired expansion of the chest and inflation of the lungs.* It is advisable to care for the oxygen supply before lobeline is injected because the anoxic depression will thus be most effectively counteracted and the risk of adding to it (by increasing the activity of the neurons when they are already suffering from severe anoxia) will be obviated. The use of analeptic drugs seems inadvisable; it is most unlikely that they could be any more effective in asphyxiated infants than they are in adults and they have been found occasionally to cause severe or fatal convulsions when given to infants even in the recommended dosage. Depression of the infant's respiratory center by narcotics given to the mother is probably a large item in severe fatal asphyxia (Cole[38] et al.). This effect is easier to prevent than to remedy; volatile narcotics, which are readily controlled and rapidly eliminated, are preferable to nonvolatile substances, and among the latter those which act for a short time are less objectionable than those with prolonged effects. The dosage should be kept as small as possible and the duration of the narcosis as brief as possible.

*According to Wilson[164] et al. the lungs of a stillborn baby cannot safely be inflated by positive pressure applied to the mouth or within the trachea, or by suction applied to the chest wall (Drinker respirator, page 705). Rupture of alveolar septa, hemorrhage, and subpleural emphysema will be produced without expansion of large areas of the lung. Perhaps this means that relaxation of the bronchial muscle, associated with a discharge of impulses from the respiratory center, plays a necessary part in the first inflation of the lung. If this is true, artificial inflation should be more effective when the bronchial muscle has been relaxed, as by adrenalin, but there is at present no information on this point. Wilson also points out that a gas exchange adequate for the basal needs of the infant whose lungs are unexpanded can be secured by intratracheal insufflation of oxygen (80 per cent) and carbon dioxide (20 per cent); it seems inadvisable to use as high a concentration as this of the latter gas, for the optimum stimulant concentration lies much lower and the concentration used to elicit narcosis in normal (not asphyxiated) subjects is not much higher.

CHAPTER XLV

ANOXIA

Anoxia means lack of oxygen, no matter where it is or how it is produced. *Anoxemia* means lack of oxygen in the circulating blood only; the two terms are not synonymous. *Hypoxemia* has recently been used to denote a reduction in the oxygen content of the blood short of the complete absence of oxygen that anoxemia implies if that term is taken literally; actually "anoxemia" has been used very widely for exactly the same purpose without any confusion, and the new word seems unnecessary. *Hypercapnia* means an increase and *hypocapnia* (or *acapnia*) a decrease in the amount of carbon dioxide in the blood; these terms imply that the oxygen content is not directly affected. *Hypercarbia* and *hypocarbia* have to do with changes in the alkali reserve. *Asphyxia* implies diminution both in the intake of oxygen and in the elimination of carbon dioxide, i.e., anoxemia plus hypercapnia; it is not a synonym for anoxia, although anoxia is one of the outstanding features of asphyxia.

THE CAUSES OF ANOXIA

Oxygen-lack may result from any one of a number of conditions. On the basis of their essential causes the anoxias have been classified by Peters and Van Slyke[126] as follows:

1. *Anoxic anoxia (anoxemia)* is reduction in the tension of oxygen in the arterial blood. It affects the entire body. It is produced by interference with the passage of oxygen from the air into the blood in the lungs (mechanical obstruction, drowning, weak respiratory movements, reduction in the size or permeability of the aerating surface by edema, exudate, consolidation, adhesions, collapse, or emphysema); by reduction in the partial pressure of oxygen in the inspired air (inhalation of inert gases such as nitrogen, hydrogen, nitrous oxide, ethylene, acetylene, helium, methane); and conspicuously by inhalation of air under reduced (barometric) pressure, as at the high altitudes reached on mountains or in flights in aircraft. Anoxemia may also be brought about by increasing the oxygen consumption until it is greater than the available supply; this can occur in very vigorous exercise even in normal subjects at sea level, but it is much more readily brought about at high altitudes or in subjects with a pre-existing defect in the pulmonary gas exchange.

2. *Anemic anoxia* is reduction in the volume of oxygen that can be furnished to the tissues by the blood. This results when the amount of hemoglobin is decreased (anemia, hemorrhage) or when the ability of the hemoglobin to yield oxygen to the tissues is decreased by poisons (carbon monoxide; agents, such as nitrites, nitrophenols, chlorates, and sulfonamide derivatives which change hemoglobin into methemoglobin). Here also the entire body is affected.

3. *Stagnant anoxia* is due to interference with the circulation. The amount of oxygen available in the blood may be normal, but if the circulation in the capillaries is impeded, the amount of oxygen reaching the tissues in a given time is less than they require. This type of anoxia may be *general* if the entire capillary circulation is sluggish (shock, hemorrhage, cardiac weakness, or low

arterial pressure for any cause, or abnormally high venous pressure, as from cardiac decompensation or venous obstruction). It may be *local* if the circulatory disturbance is local (spasm of arteries, as in Raynaud's disease, occlusion of arteries by embolism, or reduction of their size by diseases or poisons which cause gangrene). We have already (Chapter XLIV) encountered a special instance of this type in the cerebral circulation, where spasm of vessels may result from reduction in the CO_2 tension of the blood and where the capillary circulation may be impeded by rise in intracranial pressure.

4. *Histotoxic anoxia* is produced by interference with the ability of the cells to utilize oxygen, even though the supply is normal in all respects. This occurs most conspicuously in poisoning by cyanide, to a lesser extent in poisoning by alcohol and certain other narcotics.

THE EFFECTS OF ANOXIA

The central nervous system and the heart are the parts of the body from which arise most of the symptoms and practically all of the dangers of anoxia. Of all the tissues of the body these are the most sensitive to reduction in their own oxygen supply. The voluntary muscles are also affected directly, but the most serious effects of anoxia upon the muscular system are due to derangements in the central nervous system leading to faulty coordination and lack of voluntary control. Functions such as respiration, circulation, digestion, and metabolism, are altered by anoxia but the alterations are brought about by the regulating mechanisms of the central nervous system. Death from acute anoxia is due to damage to the heart and to the central nervous system. When the exposure is long-continued but less severe other tissues are likely to be involved, but changes in the central nervous system and cardiac weakness are still the most prominent features.

Fulminating Anoxia.—If anoxia of high degree is induced very rapidly (as by inhalation of an undiluted inert gas such as nitrogen, hydrogen, nitrous oxide, ethylene, helium, or methane), there will be an initial sensation of suffocation followed very rapidly by unconsciousness; in normal individuals the time required ranges from forty-five to eighty seconds. If the exposure is brief, recovery is just as rapid and quite complete when pure air is again breathed.* Such results are obtained only when the oxygen tension in the alveolar air is almost explosively reduced to a very low level, and this cannot be tolerated for more than a few minutes without danger of acute failure of the heart or of slowly reversible or irreversible damage to the central nervous system (see page 683). In such cases breathing is greatly stimulated at first and blood pressure and pulse rate are apt to increase sharply (Fig. 267), but if more oxygen is not soon supplied respiration becomes slower, and then fails entirely; blood pressure also soon begins to fall, the heart becomes slower, and soon it ceases to beat (Fig. 268). This type of fulminating anoxia is encountered daily in the use of nitrous oxide, undiluted with oxygen, in the practice of dentistry. It is also met with occasionally in mining accidents involving methane gas. A similar situation may also arise if there is a sudden failure in the source of oxygen in an airplane traveling at a high altitude; it is particularly to be

*As an example of the rapidity with which the effects of such an exposure develop and disappear, Haldane[58] cites the case of a miner who, upon raising his head into a pocket of methane, drops as though felled, recovers completely after breathing pure air for a few seconds, imagines that one of his companions had knocked him down, and acts accordingly.

expected in a sealed-cabin plane in which the occupants are breathing outside air that is mechanically compressed to a pressure approaching that found at sea level, for here a sudden leak in the cabin or failure in the compressing mechanism could cause a very rapid drop in the tension of oxygen in the inspired air (see Armstrong,[8] pp. 264, 335, and 387). Inhalation of hydrocyanic acid fumes also produces almost instantaneous unconsciousness and collapse, but the anoxia here is histotoxic, not anoxic. Inhalation of a high concentration of carbon monoxide gas will also produce almost immediate unconsciousness and collapse, but monoxide is not an inert gas since it combines chemically with hemoglobin (which the inert gases do not); recovery after an exposure to an atmosphere of CO would certainly not be as rapid as after inhalation of the other gases mentioned above.

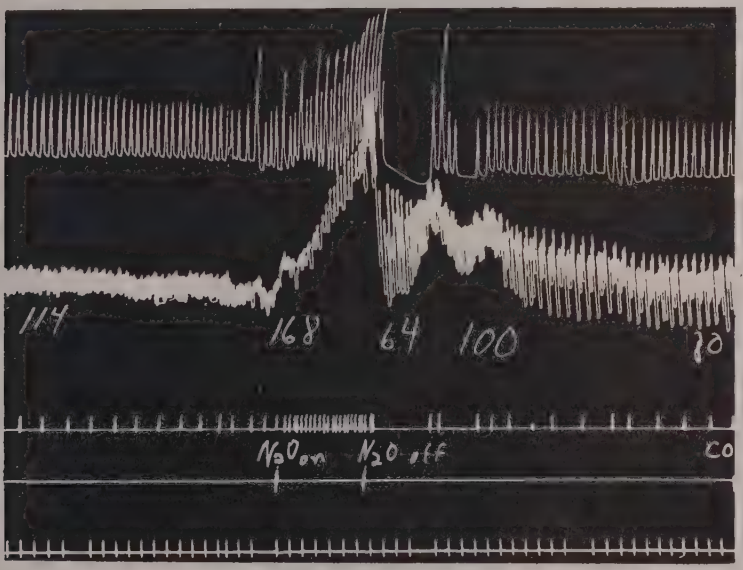

Fig. 267.—Fulminating anoxia. Dog—anesthesia by chloralose and morphine. Records (from above down): Respiration, femoral blood pressure, volume of expired air (in 500 ml.), signal, time in five-second intervals. Sinus and vagodepressor nerves intact. Between signals nitrous oxide (undiluted) was inhaled through the inspiratory valve. Note hyperpnea, hypertension, and cardiac acceleration (figures for pulse rate are directly under the blood pressure record). Note also apnea and fall in blood pressure immediately after removal of N_2O (i.e., after one breath of air).

Acute Anoxia.—As a rule, a deficiency of oxygen of a degree sufficient to produce definite symptoms does not appear instantaneously but develops more gradually. We shall deal later with anoxia due to disease and confine our attention at present to anoxia produced in normal individuals by changes in the environment. An outstanding example is exposure to an atmosphere containing a reduced amount of oxygen per volume of air breathed, as at the high altitudes encountered by aviators, mountain climbers, and travelers in mountainous country; similar situations may be created intentionally in the laboratory by exposing the subject in a closed chamber to an atmosphere under the reduced pressure cor-

responding to a high altitude, or by causing him to breathe air containing an abnormally high proportion of nitrogen, or by allowing him to breathe the same air in and out of a container with provision for absorbing the expired CO_2, so that he is exposed to a steadily decreasing oxygen tension as a result of his own consumption of the gas. In all such cases there are fewer oxygen molecules per ml. of inspired air and those present diffuse less readily. Another outstanding example—and one of great importance because it is likely to be encountered by any physician—is exposure to carbon monoxide. The effects of acute anoxia

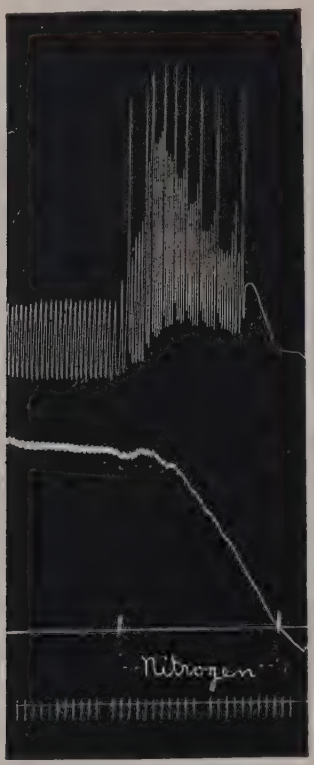

Fig. 268.—Effect of fulminating anoxemia on respiration and blood pressure. Cat—pentobarbital narcosis. Respiration recorded by plethysmograph, blood pressure by mercury manometer connected with femoral artery. Vagodepressor and sinus nerves intact. Inhalation of nitrogen (undiluted) until respiration failed. Note dyspnea followed by respiratory failure while blood pressure was falling rapidly because of cardiac depression. Time record shows five-second intervals.

produced in otherwise healthy subjects by any of these means are substantially the same. Different individuals vary considerably in their capacity to resist anoxia, and there are certain variations dependent upon the circumstances of the exposure (muscular exercise, rapidity of development of the anoxia, duration of the exposure, previous exposures not fully recovered from). On the whole, however, the symptoms which result from anoxia of a given degree of

severity are quite similar no matter how the condition is produced.* The chief symptoms arise from the central nervous system, the circulation, and the voluntary muscles.

The Central Nervous System.—The effects of acute anoxia bear striking similarities to those of acute alcoholism;[12, 13, 67, 113] this is best seen when muscular exertion and consequent fatigue are not a factor, and since the best example of this—ascent in aircraft—is also one of the most important practically (other examples are travelers ascending a mountain by a railroad, victims of poisoning by carbon monoxide, and subjects of a laboratory experiment), we shall now deal entirely with the symptoms and physical signs that are likely to be encountered during flight from sea level to a high altitude. Krogh[95] points out that animal flight (by birds) involves stresses greater than any other form of muscular activity; flight by man (in aircraft) also involves stresses that are new to the mammalian organism and against which it is without adequate protection. Perhaps the chief hazard is the absence of physical or mental discomfort, pain, or distress, to give warning of the presence of anoxia of a dangerous grade. This is because the cortical cells involved in the perception of sensations of pain or discomfort are among the first to be inactivated by progressive anoxemia (see page 683), so that the usual warning signals pass unheeded at the time; they are perceived only after the anoxemia has been relieved, presumably because the cortical cells recover more rapidly than the structures from which the sensations of pain and discomfort arise. Table XXIV, reproduced from Armstrong's book, will aid the reader in understanding the relation of altitude to anoxia.

TABLE XXIV

BAROMETRIC PRESSURE AT VARIOUS ALTITUDES*

ALTITUDE FEET	PRESSURE MM. HG	ALTITUDE FEET	PRESSURE MM. HG	ALTITUDE FEET	PRESSURE MM. HG	ALTITUDE FEET	PRESSURE MM. HG
0	760.0	21,000	334.8	41,000	134.2	61,000	51.6
1,000	733.0	22,000	320.8	42,000	127.9	62,000	49.2
2,000	706.6	23,000	307.4	43,000	122.0	63,000	46.9
3,000	681.0	24,000	294.4	44,000	116.3	64,000	44.7
4,000	656.4	25,000	282.0	45,000	110.9	65,000	42.6
5,000	632.4	26,000	269.8	46,000	105.7	66,000	40.7

*From Armstrong: Principles and Practice of Aviation Medicine, Baltimore, 1939, Williams and Wilkins.

At altitudes lower than 12,000 feet (483 mm. barometric pressure or about 100 mm. oxygen pressure, corresponding with inhalation of about 13 per cent oxygen at sea level) most subjects have no symptoms and show no signs other than a moderate increase in respiratory activity of which they usually are unaware. At or above this altitude some or all of the following symptoms are likely to develop: sleepiness, headache, lassitude and fatigue, or a sense of comfort and well-being, a feeling of self-satisfaction associated with outbursts of hilarity or quarrelsomeness, and, in any case, breathlessness; frequently a vague, elusive feeling of distress or anxiety appears, indicating that the signals of danger are indeed present though imperfectly apprehended. Signs of muscular incoordination begin to make

*In carbon monoxide poisoning respiration is not stimulated as it is in anoxia of comparable severity produced by most other means (see page 692).

their appearance, and although simple, familiar movements may be performed about as well as usual, more complicated or unusual ones are clumsily and imperfectly executed. As the exposure continues muscular movements in general become slower and weaker, tremors appear, and finally paralysis develops. This begins in the legs and ascends until the arms and neck are also involved. At the same time memory is blunted and the sense of judgment and the capacity for self-criticism are impaired, so that the victim is unaware of his shortcomings and inefficiency; on the contrary, he is apt to be convinced that he is staging a remarkably good performance, and afterward he has no recollection of any difficulties encountered. Visual acuity begins to be impaired at about 15,000 feet, hearing at about 16,000-18,000. Pain perception and the appreciation of time are interfered with quite early. Above 20,000 feet muscular twitchings or clonic movements may appear and a striking fixity of purpose becomes evident: the subject now is incapable of reasoned judgment but instead persists with great tenacity in doing whatever task he is engaged in regardless of the consequences. Unconsciousness usually ensues at about 25,000 feet (oxygen pressure about 59 mm., corresponding with inhalation of about 8 per cent oxygen at sea level); by this time the victim may be unable to move and almost blind and deaf, yet he may not have been aware at any time of any abnormality. Death apparently is due to paralysis of the respiratory center in subjects with normal hearts, but the anoxia of high altitudes will greatly exaggerate any preexisting cardiac weakness, and cardiac failure may occur at relatively low altitudes in such individuals.

The circulation shows an increase in pulse rate beginning at about the same level as that at which the respiratory response begins (i.e., anywhere between 4,000 and 12,000 feet) and progressing up to the point of collapse. The average increase in normal subjects is about 28 beats per minute, but it may be considerably greater than this. The *blood pressure* also should begin to increase at the same time as the pulse rate and the increase in systolic pressure is progressive until collapse occurs. The rise in pressure should amount to 15 to 20 mm. but in some subjects the pressure falls quite early (apparently because of failure of the vasomotor center) and in these fainting is apt to occur. Cyanosis usually is present, but in subjects who faint pallor is seen instead. The *blood* shows no significant increase in hemoglobin or number of erythrocytes during short (four hour) exposure to 12,000 feet (Armstrong,[8] p. 269); the characteristic adaptation to high altitudes (page 691) apparently requires continuous exposure for a fairly long time. The *heart muscle* is depressed by anoxia; although Armstrong[8] (p. 268) has found that the hearts of experimental animals continue to beat for five or ten minutes after respiration has failed at high altitudes, the blood pressure (hence the amount of work done by the heart) apparently is very low under such circumstances, and it is most probable that the heart will fail very rapidly when exposed to severe anoxemia if the demands made upon it are of a normal order; from this viewpoint fainting at a high altitude is a protective reaction which safeguards the heart by lowering the blood pressure and thus diminishing the work demanded of the cardiac muscle. There is no doubt that exposure to the anoxemia of high altitudes is especially dangerous for subjects with impaired heart function.

The accompanying chart (Fig. 269) taken from the "Air Service Manual" of the United States Army depicts the results obtained in a normal individual when the oxygen content of the inspired air is gradually lowered by rebreathing while the exhaled carbon dioxide is absorbed. This particular subject withstood oxygen deficiency without alarming symptoms until a percentage of a little more than 6 was reached—a figure that corresponds with a barometric pressure of 217 mm., an altitude of about 31,000 feet, and an oxygen tension of about 44 mm. in the inspired air (159 mm. at sea level). Respiratory minute volume did not change significantly until the oxygen content of the inspired air had fallen nearly to 12 per cent, which corresponds with a barometric pressure of 434 mm., an altitude of about 14,500 feet, and an oxygen tension of about 91 mm. in the inspired air. As we have already seen (page 565), Ellis[52] has found that some subjects show a perceptible increase in respiratory minute volume when the oxygen content of the inspired air is reduced only to 18 per cent (corresponding with an altitude of about 4,000 feet). A significant hyperpnea usually begins only at about 14 per cent oxygen (12,000 feet, 483 mm. barometric pressure, 123 mm. oxygen tension in the inspired air), and the respiratory minute volume is doubled in most men by the time 8 per cent oxygen is reached (about 24,500 feet, 289 mm. barometric pressure, 60 mm. oxygen tension).

In mountain climbers breathlessness and fatigue are the most prominent symptoms, but this is because such subjects are exerting themselves more than the aviator. The greater

breathlessness is due to the greater carbon dioxide production consequent on muscular activity; the chemical stimulus to the respiratory neurons is not reduced to as low a level by the reflex hyperpnea of anoxemia as it is in subjects who are not exerting themselves and the center is therefore more strongly stimulated at a given grade of anoxemia. Another factor operating in the same direction is the relatively high CO_2 tension in the blood associated with muscular exercise at high altitudes; the alkali of the blood, which is prominently concerned in the transport of CO_2 (Chapter XLIII), is diminished by anoxia, and as a result an unusually large proportion of the total amount of CO_2 must be carried in solution and the CO_2 tension of the blood is easily raised. This breathlessness protects the mountain climber from foolhardy exposure to anoxia of a dangerous degree because he becomes much

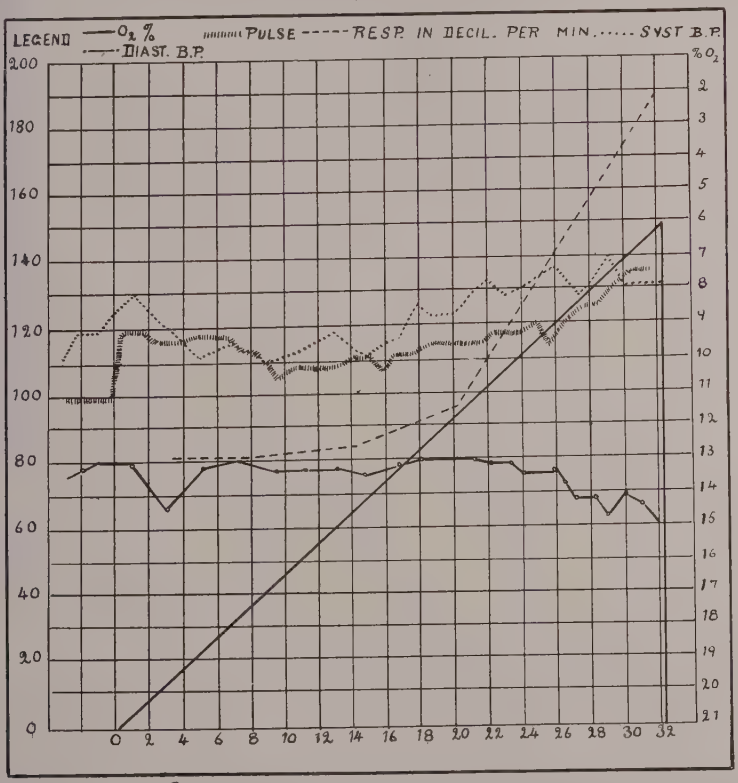

Fig. 269.—Response of a normal young man to progressive anoxemia. At start, records (from above down) show: Systolic blood pressure, pulse rate, respiratory minute volume (in 100 ml. units), diastolic blood pressure (key given at top of chart). Vertical ordinates: figures on left apply to blood pressure (mm. Hg), pulse rate, and respiratory minute volume; figures on right indicate percentage of oxygen in the inspired air, change of which is shown by continuous diagonal line. Abscissa: time in minutes. (U. S. Air Manual Chart.)

more uncomfortable than is the case with one who is borne upward without exertion on his part. The same increase in the CO_2 tension of the blood which causes breathlessness in mountain climbers may also safeguard their mental processes by keeping their cerebral blood vessels from constricting as they otherwise would when respiration is stimulated by anoxia (see page 610). The fatigue and muscular weakness of mountaineers are doubtless due in part to impairment of the oxidative processes in the muscles, in part to interference with the central nervous processes concerned with voluntary movement.

In the victim of *carbon monoxide poisoning* there is a greater tendency to fainting and unconsciousness and less respiratory distress than in anoxemias of comparable severity produced by other means (Haldane[67]). This is partly because monoxide has a dual effect on the hemoglobin of the blood: it diminishes the amount of oxygen that can be carried by the arterial blood and also makes the blood in the capillaries cling more tenaciously to whatever oxygen it contains (Peters and Van Slyke[126]). Consequently, the anoxia produced by monoxide is much more severe than would be expected from the degree of anoxemia (reduction in O_2 content of the blood) that is present, and the subject's heart and central nervous system are more dangerously poisoned than is at first apparent. Furthermore, in CO poisoning the oxygen tension of the arterial blood is normal though the amount of oxygen available to the tissues is reduced; consequently the receptors of the carotids and aorta are not stimulated although the tissues in general do not get enough oxygen.

The severity of the symptoms elicited by exposure to a deficient supply of oxygen is determined not only by the degree of the deficiency but also by the duration of the exposure. In the case of anoxia due to carbon monoxide these relationships have been worked out quite precisely (see page 693). Although the corresponding data for exposure to high altitudes have not as yet been obtained there is no doubt that the same general relationships exist here also. This same question, as it concerns the problem of flight in aircraft, is discussed by Armstrong.[7, 8] During the first World War it was found that aviators who made frequent flights at high altitudes without oxygen showed much greater fatigue and "staleness" than others who carried out similar assignments using oxygen. Some of the former developed a characteristic neurosis in which emotional instability, loss of self-reliance, suppressed anxiety, lack of initiative, muscular tremors, and disturbed sleep were outstanding symptoms.[113] As this syndrome developed the flier had to be kept at lower and lower altitudes and finally he became entirely unfit for flying although perfectly fit physically. Subsequent experience in civilian aviation has been very similar to this (see Armstrong,[8] pp. 279 ff.). There is no doubt that repeated exposures to reduced oxygen pressures can produce marked deterioration in cerebral functions. Evidently the brain does not recover completely from a brief exposure to severe anoxia, or from a prolonged exposure to moderate anoxia, until many hours (twenty-four to seventy-two hours—Armstrong[8]) have elapsed, and the more severe the anoxia or the longer the exposure, the longer the time required for complete recovery. If the exposure is repeated before recovery has taken place, it will have cumulative effects, i.e., the derangements produced by today's exposure are superimposed on the remains of yesterday's. The most vulnerable parts of the brain then show signs of damage between exposures. The situation here is undoubtedly very similar to that encountered after prolonged inhalation of nitrous oxide and oxygen; in some subjects this produces permanent degenerative lesions in various parts of the brain (Courville[92]). This shows that moderately severe anoxemia, continued over the relatively brief period of ordinary surgical anesthesia, is quite capable of producing irreversible changes in the central nervous system in some subjects, at least. We can safely conclude that there is a narrow and uncertain margin of safety between completely and promptly reversible neuronal derangements, on the one hand, slowly reversible or irreversible changes on the other.

Chronic Anoxia.—The effects of prolonged or repeated exposure to a subnormal supply of oxygen resemble fatigue just as closely as those of acute exposure resemble drunkenness (Barcroft[12, 13, 15]). The resemblance refers to mental as well as to muscular fatigue, and this fact is a matter of considerable interest to the physician.

The symptoms of acute anoxia do not disappear immediately when the normal oxygen supply is restored. If the exposure is short, the *aviator* as he returns from a flight at a high altitude, the *traveler* who has spent only a few hours on a mountain top and then returns to a lower altitude, or the *subject of a laboratory experiment* as the oxygen pressure is increased from a severely low level, notices first that lights are brighter and sounds are louder. Muscular power, judgment, and self-criticism return. By the time the surroundings have become normal there may only be a blank memory and a severe headache to remind the subject of his experience, although breathing and pulse are likely to be abnormally slow for some time. The longer the exposure lasts, the slower is the recovery when normal conditions are restored. Emotional disturbances, nausea, or weakness may continue after the subject has returned to

sea-level conditions, and may, in fact, appear only after the return to sea level if the sojourn at the higher altitude did not last long enough for these symptoms to develop there.

In the *dweller at high altitudes* compensatory factors come into play (see page 688), and the central nervous effects of acute anoxia become progressively less marked. Some of them remain in the form of decreased patience with one's self or with one's fellows, lessened ability to concentrate, decreased quality in the performance of tasks involving mental or physical work, and greater liability to fatigue, mental as well as muscular. Sleep is likely to be fitful, interrupted by dreams, and not refreshing. Pulse rate and blood pressure become normal again (Lutz and Schneider[107]) but breathing remains deeper and faster than at sea level. Muscular capacity improves, but it is less than normal, partly because shortness of breath promptly ensues, partly because the oxidations within the muscles are not as well carried out as they should be. Fatigue results from relatively slight exertion and recovery is unusually slow, with an undue amount of stiffness.

Natives who spend their entire lives at high altitudes become completely acclimatized, but occasionally they suffer from a set of symptoms which are known as *chronic mountain sickness*. The symptoms include headache, hoarseness, loss of appetite, weakness and pains in the extremities, visual disturbances, transient spells of stupor or coma. They occur without obvious cause in persons who have lived for many years without symptoms at the same altitude; they are likely to disappear spontaneously but to return with increasing severity. The cause is unknown: these patients show the same changes in the blood and in the chest as other natives symptom-free at the same altitude, and there is no evidence that any of the mechanisms of acclimatization are at fault. Talbot and Dill[156] in discussing the possible causes, point out that pathological changes may occur in the tissues after many years of exposure to subnormal oxygen tensions; they also suggest the possible influence of the abundance of ultraviolet rays at high altitudes. Apparently no one is immune to chronic mountain sickness, provided that he lives at a sufficiently high altitude for a sufficiently long time. There is experimental evidence to indicate that degenerative changes may occur in the organs of individuals who remain at high altitudes. Campbell[32] found that rabbits, rats, and mice kept under an atmosphere corresponding to that on Mt. Everest (30,000 feet—7 per cent oxygen) lost weight and eventually died; at autopsy fatty degeneration of the heart muscle and of other viscera was disclosed.

THE SIGNIFICANCE OF ANOXIA

The similarity between the symptoms of acute anoxia and those of acute alcoholism has already been alluded to. A feeling of comfort, well-being, and self-satisfaction, impairment of muscular coordination, distortion of judgment, emotional instability, blunting of sensory perceptions, loss of the power of self-criticism, loss of memory, and finally loss of consciousness—all these are common to both conditions and denote effects upon the central nervous system. Does this mean that alcohol and anoxia affect the central nervous system in the same way? The narcotic action of alcohol probably is due to an interference by it with the intracellular oxidative reactions upon which nerve cell function depends, and according to current conceptions[91, 133] this interference is exerted first and foremost on the dehydrogenating part of the cell enzyme system. Under such circumstances oxygen is taken up and activated in a normal manner, but it does not combine with hydrogen as it should (i.e., the oxygen carriers are normally oxidized but imperfectly reduced (see Chapter XLVII). Anoxia presumably acts by interfering with the uptake of oxygen by the cell simply because fewer molecules of oxygen are available for the process; the rate at which they diffuse into the cells may also be diminished. The end result, as far as the capacity of nerve cells to carry on their specialized functions is concerned, would be the same in anoxia as in narcosis, i.e., their ability to respond to stimuli would be decreased because the energy-yielding reactions which lead to the instability (excitability) on which the specialized functions depend are not properly carried out (see page 562). The similarity between the cerebral effects of alcohol and those of anoxemia indicates that the various brain cells have the same susceptibility to the two influences. The cerebral functions most recently acquired in man's evolutionary development (judgment, reason, self-criticism, self-control) are most susceptible to alcohol and to narcotics, while the more primitive functions concerned with muscular control are more resistant, and the most primitive ones (control of respiration, circulation, etc.) are most resistant of all. The reason for these differences in susceptibility is probably the same in both cases, i.e., differences in complexity of the various neuronal systems.

The highest cerebral functions presumably involve a larger number of neurons (which individually may also be more complex) and more synaptic communications, than the more primitive processes; since the entire organization is maintained in a reactive state by oxidative reactions within the individual neurons, a given degree of interference with these oxidations naturally manifests itself first and foremost in those parts in which the most cells are concerned in the normal response. Another probable factor in these differences in susceptibility is a difference in the strength of the excitation process; the disturbances which normally activate the higher cerebral functions probably are distinctly weaker than those involved in muscular movements and those concerned in the regulation of medullary functions are probably the strongest of all (page 663). If the excitability of the entire system is reduced to the same extent, either by alcohol or by anoxia, the weaker signals would naturally become ineffective before the stronger ones.

In *chronic anoxia* the resemblance to muscular fatigue has been stressed for a number of years (Barcroft), and there is ample reason in the known facts of muscular contraction to account for this resemblance. We are entitled to believe that the muscles actually become fatigued more readily because the blood contains a subnormal supply of oxygen. A similar relation between anoxia and fatigue of the central nervous system was also pointed out by Barcroft[14] and has aroused considerable interest on the part of neurologists and psychiatrists (see McFarland[113]). When we peruse the list of the symptoms of chronic anoxia, as encountered in aviators and in dwellers at high altitudes, we find a close resemblance to the symptoms of an impending nervous breakdown or with those of an established neurosis. Decreased patience, emotional instability, lessened ability to concentrate, constant fatigue, unrefreshing sleep, muscular twitchings, loss of self-confidence, anxiety—these are phenomena which the physician frequently encounters in patients who are not suffering from anoxia of any demonstrable cause. There is as yet no evidence to indicate that lack of sufficient oxygen, or a perversion in the normal oxidative processes of the cerebral cells, is responsible for the neuroses and psychoses which form a large and ever-growing problem of modern life, but the possibility is an attractive one. Abnormal contraction of the cerebral blood vessels has long been regarded as a probable factor in producing functional disorders of the brain, and this would mean stagnant anoxia. Loevenhart and his co-workers[101] found that inhalation of CO_2 produced temporary relief in some severe psychoses, and this has been repeatedly confirmed; the most probable explanation of the improvement is that it is due to relaxation of spasmodically contracted cerebral blood vessels. Yet we must not lose sight of the undoubted fact that the function of cerebral nerve cells can be altered by many agencies of which anoxia is only one; the end-result may be the same although the cause is entirely different. The fact that the symptoms of chronic anoxia are similar to those of certain functional disorders of the brain may only mean that the same nerve cells are deranged in both but for entirely different reasons.

It is a striking fact that the defenses of the body against anoxia are usually kept in reserve and are drawn upon only in emergencies. Under ordinary circumstances the call for oxygen is met by the respiratory stimulant action of CO_2 alone. As a rule, increased call for oxygen and increased production of CO_2 run hand in hand, and the stimulant action of CO_2 on the respiratory center brings about the increased pulmonary ventilation required to meet the call for oxygen. This is a fortunate provision because CO_2 is not as harmful to the cells as anoxia, because CO_2 works more rapidly by reason of the ease with which it penetrates cells, and because CO_2 has a specific action in regulating the tone of cerebral blood vessels. As long as respiration is regulated by CO_2 the central nervous system is in little danger.

The hyperpnea due directly to oxygen-lack is different in several important respects from that due to CO_2 excess. In the first place, the response to anoxemia is mainly due to reflexes from the chemoreceptors, while that to CO_2 is the result of the direct effect of CO_2 upon the respiratory center. A possible reason for this peculiar location of a defense against anoxia has been suggested on page 597. Also, the sensitivity of the reflex receptors to oxygen-lack is much less than the sensitivity of the center to CO_2. Ellis[52] found that it is necessary to reduce the oxygen in the inspired air to about 8 per cent (normal about 21 per cent) to double the volume of breathing, whereas Haldane and Priestley[68] found an increase of 0.22 per cent in the CO_2 content of the alveolar air sufficient to do the same thing. Further, CO_2 seems to be a specific dilator of cerebral blood vessels as well as a specific stimulant to breathing, so that as long as the CO_2 tension of the blood rises the entire central nervous system will get more blood; but once anoxemia begins to drive respiration, the CO_2 tension of the blood is reduced and the cerebral vessels are likely to constrict because the constrictor effect of lowered

CO_2 tension is stronger than the dilator influence of decreased oxygen tension. In this way a vicious circle is set up: anoxemia stimulates breathing reflexly, lowers the CO_2 tension of the blood, and causes constriction of the blood vessels supplying the brain, thus increasing the anoxia to which the nerve cells are subjected. Finally, in extreme anoxia, there is an acidosis as the result of incomplete oxidations in the tissues[93]; this is almost a terminal event—an expression of extreme derangement in the metabolic activity of the cells.

CYANOSIS

The term *cyanosis* simply designates a blue color imparted to the skin or mucous membranes (or any other vascular bed) by a change in the chemical composition of the blood. Cyanosis is always due to a change in the blood and the color disappears when the blood is expelled from the tissue under observation; this fact distinguishes it from the coloration due to deposition of material (e.g., silver) outside the blood vessels. The most frequent and most important cause of cyanosis is an unusually large concentration of reduced hemoglobin in the blood, and this occurs in anoxemia or in stagnant anoxia. In the anemic and histotoxic forms of anoxia and in poisoning by carbon monoxide cyanosis does not occur, for reasons to be explained later. Cyanosis is also produced by the formation of any dark hemoglobin derivative, such as sulfhemoglobin or methemoglobin.

The blue color in cyanosis is due to the absolute concentration of reduced or otherwise unoxygenated hemoglobin in the capillaries and not to the relative proportions of reduced and oxygenated hemoglobin. It has been found (Lundsgaard[104, 105]) that about 5 grams of reduced hemoglobin per 100 ml. of capillary blood, or an oxygen unsaturation of 6.70 ml. per 100 (since 1 Gm. of hemoglobin can combine with 1.34 ml. of oxygen) is about the threshold level at which cyanosis appears. Consequently, an anemic subject who has less than 5 Gm. of hemoglobin per 100 ml. of blood (= an oxygen capacity of about 7 ml. per 100 or less) cannot usually become cyanotic. The cyanotic color in the skin or other surface is mainly due to the color of the blood in the capillaries. Since the blood is continually giving up oxygen during its passage through the capillaries the average unsaturation of the blood in its transit through them may be taken as the mean between the arterial and venous unsaturations; thus if A is the oxygen unsaturation of arterial and V that of venous blood, $\frac{A+V}{2}$ gives the average unsaturation of capillary blood. Normally, arterial blood is about 95 per cent saturated with oxygen; with a capacity of 21 ml. of oxygen per 100 this means that A = about 1 ml. of oxygen unsaturation per 100 ml. under normal conditions. Venous blood normally contains about 15 ml. of oxygen per 100, so that it is roughly 70 per cent saturated and V = about 6 ml. of oxygen unsaturation per 100. $\frac{A+V}{2}$ therefore would normally be 3.5 ml. of oxygen unsaturation, or about 2.6 Gm. of reduced hemoglobin, in each 100 ml. of blood in the capillaries. This must be practically doubled for cyanosis to occur, and it is evident that such a result could be obtained: (1) by increasing A with the arteriovenous oxygen difference unchanged (as in anoxemia, where the amount of reduced hemoglobin in the arterial blood is greater than normal), or (2) by increasing V with the arterial blood normally oxygenated (as by an increase in the utilization of oxygen by the tissue under observation, or by a decrease in the blood flow through it), or (3) by increasing both A and V at the same time (as in

muscular exercise in the presence of anoxemia, or in heart disease, where the aeration of the blood in the lungs may be impeded by fluid in the air passages while the circulation in the tissues is also abnormally slow).

Factors Which Modify Cyanosis.—Lundsgaard and Van Slyke[105] have pointed out that although the oxygen unsaturation of the blood in the capillaries is undoubtedly the real cause of cyanosis, there are other factors which modify the intensity of the color and which may influence the threshold concentration of reduced hemoglobin required to produce cyanosis. The most important of these factors are: (1) the thickness of the avascular epidermis, which may conceal to varying degrees the color in the capillaries; (2) the amount of pigment in the skin, whether normal (sunburn, or the deep pigment of the black and yellow races) or pathological (jaundice, argyria, Addison's disease, etc.); (3) variations in the color of the blood plasma, due to differences in the amount of pigment or lipoid in it, possibly also to large increases in the leucocytes, as in leucemia; (4) variations in the amount of oxygenated hemoglobin in the blood; (5) variations in the number, width, and length of blood-filled capillaries in a given area, including short circuits between the arterial and venous channels (arteriovenous communications); (6) deviations of the average capillary blood from its normal mean position between arterial and venous. These factors cannot produce cyanosis, but they can alter the amount of oxygen unsaturation needed to produce it as well as the final color produced.

Causes of Cyanosis.—1. *Increase in the Amount of Reduced Hemoglobin in the Arterial Blood.*—Cyanosis due to incomplete oxygenation of the blood is the most severe type and usually the most important from the standpoint of diagnosis and treatment. It should be made clear that while the presence of cyanosis (if due to abnormally large amounts of reduced hemoglobin in the capillaries) means that anoxia is present, the absence of cyanosis does not necessarily mean that anoxia is absent. The color of the skin is more directly related to the oxygen unsaturation of the arterial than to that of the venous blood, whereas the oxygen uptake by the tissues is more closely related to the oxygen unsaturation of the venous blood. Cyanosis increases with the amount of hemoglobin present because at a given oxygen unsaturation there will be more reduced hemoglobin; there may be marked cyanosis in conditions of *polycythemia* with little or no anoxemia. *Anemia*, on the contrary, decreases the tendency to become cyanotic while increasing the likelihood of anoxia. Acclimatization (page 688) reduces the symptoms of anoxia but cyanosis remains unchanged. *It is only in conditions in which anoxia is due primarily to imperfect oxygenation of the blood, in which the hemoglobin content of the blood remains unaltered, and in which the onset and course are too rapid for acclimatization to occur, that a close parallelism exists between cyanosis and anoxia. Such conditions exist in pneumonia and probably in other acute anoxias arising from interference with the gas exchange in the lungs.*

a. *Conditions in which the primary fault lies in the aerating surfaces in the lungs.* A characteristic example is the state of affairs in *lobar pneumonia*. Cyanosis in this disease is not entirely due to the reduction in the aerating surface by the consolidation, for in the consolidated areas the circulation may be obstructed and the blood therefore must pass through well-ventilated alveoli. But in some of the consolidated areas the vessels remain patent, and the blood passing through these emerges as venous as it entered. Fluid may be present in the finer respiratory passages and this interferes with the passage of air into alveoli in which the circulation is normal. Respiration is typically rapid and shallow in this disease, partly because of pleurisy which leads to voluntary restriction of the respiratory movements, partly because of a direct effect of the toxins upon the center; the impaired respiration adds to the anoxemia. The arterial blood leaving the lungs is a mixture of that which has been oxygenated and that which has not, and in severe cases there may be marked cyanosis, with the arterial blood only 75 per cent saturated with oxygen; this means an arterial oxygen content equal

to that normally seen in venous blood (15 ml. per 100). *Cyanosis is often more marked in bronchopneumonia than in lobar pneumonia* because the disease process is widely scattered, there is considerable fluid in the air passages, and the circulation in the consolidated alveoli is not abolished.

In cases of *obstruction of the trachea or bronchi* cyanosis results for obvious reasons. In *asthma* cyanosis occurs because the movement of air in and out of the alveoli is hindered by contraction of the bronchial muscle. In *emphysema* cyanosis may be very marked, partly because the chest is permanently in the inspiratory position and cannot be expanded much further, partly because many of the septa between the alveoli are obliterated and the area available for the gas exchange (both vascular and epithelial) is reduced. In *acute pneumothorax* cyanosis often occurs because the movement of air in and out of the collapsed areas is impeded while the circulation continues in them; in chronic pneumothorax the vessels become obliterated and cyanosis may be absent.

b. *Conditions in which the primary fault is insufficient pressure of oxygen in the alveolar air.* Exposure to the low barometric pressures found at *high altitudes* produces cyanosis and this is likely to occur when the pressure is reduced to about two-thirds of its sea-level value, i.e., to 500 mm., corresponding to an altitude of about 11,000 feet. The cyanosis persists after acclimatization. A similar situation may be created by *shallow breathing* even at sea level, for the air in the alveoli is not properly renewed and its oxygen tension falls. Rapid shallow breathing may be encountered in *neurasthenia, after gassing,* or in certain forms of *encephalitis.* One of the dangers of these conditions is that the respiratory center does not get a period of complete rest and it may become fatigued. Deep breathing is beneficial in such cases.

c. *Conditions in which the primary fault is an abnormal mixture of arterial and venous blood.* The characteristic form is seen in *congenital heart disease,* in which there is intense cyanosis in about half the cases. The cyanosis is of course partly due to direct mixture of blood between the two auricles, but not entirely so because oxygen inhalation relieves it considerably; this indicates that the low arterial oxygen saturation which these patients show is due to a considerable extent to imperfect oxygenation of the fraction of the blood which flows through the lungs. The intense cyanosis is also due to some extent to the polycythemia which is usually present; a given unsaturation of arterial blood would mean an unusually large amount of reduced hemoglobin in the capillaries.

In collapse, consolidation, or obstruction of the air passages as long as the circulation continues in the alveoli which are imperfectly aerated (if at all) the blood emerging from the lungs is also a mixture of oxygenated and unoxygenated.

2. *Cyanosis Due to Abnormal Reduction of Oxyhemoglobin in the Systemic Capillaries.*—This may be due either to increased utilization of oxygen by a tissue or to decreased flow of blood through it; the latter is the usual cause of cyanosis of this type, for whenever the metabolic activity of a tissue is increased the circulation is increased in proportion to its increased need for oxygen. Thus in *severe muscular exercise* cyanosis may occur in the face but the active muscles show little or none. Here the cyanosis is probably due to vasoconstriction in areas which do not participate directly in the increased activity, so as to divert more blood to those that do. *Chilling* of a part of the body causes cyanosis because the blood vessels constrict; excessive cold may reduce the metabolism of the chilled part and it then loses its blue color and becomes pale. In *heart disease* the peripheral circulation becomes abnormally sluggish and this is a factor in the production of the cyanosis which develops.

To produce cyanosis solely as the result of increased utilization of oxygen by the tissues the blood must lose 6 ml. more of oxygen per 100 than it ordinarily does, which means the development of *more than double the normal arteriovenous oxygen difference of 5 ml. per 100;* the oxygen consumption would have to be more than doubled.

3. *Cyanosis Due Both to Decreased Oxygenation of Arterial Blood and to Increased Reduction of Oxyhemoglobin in the Tissues.*—This is seen in the ap-

pearance or exaggeration of cyanosis in individuals at *high altitudes when they indulge in physical exercise.* It is seen in patients with *heart disease,* for in them the oxygenation of the blood in the lungs is hampered by fluid in the air passages and the peripheral circulation is sluggish; there may be no cyanosis until the patient exerts himself or it may be present continually, depending on the severity of the condition. The *asthmatic* or *emphysematous* subject is in a similar situation.

4. *Cyanosis Due to Alterations in the Hemoglobin.—Methemoglobin* is produced by a number of drugs and poisons among which nitrites, acetanilid, aniline, nitrobenzene, the nitrophenols, sulfanilamide and its congeners, and chlorates are conspicuous. The iron is changed to the trivalent form and cannot combine reversibly with oxygen. Such hemoglobin is dark in color and cyanosis appears as a result. The oxygen tension of the blood, however, is normal and the subjects may have no respiratory symptoms of anoxia although they are deeply cyanosed. The color of the skin is due to the methemoglobin, not to reduced hemoglobin.

Sulfhemoglobin is rare in its appearance and the conditions responsible for its formation are not yet understood. It is not formed in poisoning by sulfides because they are rapidly transformed to sulfates in the body, but in cases of sulfhemoglobinemia there is a strong reducing agent of unknown composition in the blood, urine, and saliva, and the suggestion has been made that because of this agent the minute amounts of H_2S normally absorbed from the bowel can convert hemoglobin into sulfhemoglobin.

In poisoning by carbon monoxide there is no cyanosis because carboxyhemoglobin is red, not blue, and the blood passes through the capillaries with less than the normal amount of reduced hemoglobin in it. *In poisoning by cyanide or other agents which produce a histotoxic anoxia there is also no cyanosis* because the tissues take less oxygen out of the blood than normally, and there is therefore less reduced hemoglobin in the capillaries than would ordinarily be the case.

COMPENSATIONS FOR ANOXIA (ACCLIMATIZATION)

When a normal individual first moves to a high altitude, he suffers from the usual symptoms of acute anoxia: breathlessness, nausea, vomiting, headache, palpitation, muscular weakness and incoordination, interference with mental processes, dimness of vision, partial deafness. The relation of the symptoms to the ascent of mountains has long been recognized and the term *mountain sickness* is applied to them. After a time (usually several days) the symptoms diminish in severity and some of them may eventually disappear entirely. The individual is now able to carry on a much greater amount of physical and mental exertion than was possible at first. *Acclimatization* has taken place. The most important factors responsible for this remarkable ability of the normal body to secure the oxygen it requires are *an increase in the rate and depth of breathing and an increase in the ability of the blood to transport oxygen.* In addition, it is probable that the tissues become adapted in some unknown way to a lower pressure of oxygen than that to which they were accustomed.

The rate and depth of breathing increase, the change in rate being proportional to the altitude (Haldane,[67] Barcroft[12]). As a result of the increased depth of breathing the oxygen tension in the alveolar air approaches that of the inspired air more closely than is the case when breathing is shallower, and the

blood is therefore exposed to a higher tension of oxygen. Thus, at 10,000 feet the alveolar oxygen tension would be 59 mm. and at 15,000 feet 33.8 mm. if the oxygen tension of alveolar air remained as much below that of the inspired air as it does at sea level. Actual determinations show a tension of 65 mm. at 10,000 feet and 52 mm. at 15,000 feet, the added pressure of oxygen in the alveoli being due to increased movement of air in and out of them. The increase in breathing is due to reflexes from the carotid and aortic bodies and the CO_2 content of the blood is accordingly reduced. The CO_2 tension in the alveolar air falls correspondingly. To compensate for the alkalosis which results from the lowered CO_2 tension there is an increased excretion of alkali by the kidney and

the total amount of base in the blood is decreased. As a rule, this excretion of alkali does not quite compensate for the lowered CO_2 content and the hydrion concentration of the blood remains slightly more alkaline than at sea level (Barcroft,[15] Peters and Van Slyke[126]). We have already seen (page 680) that the reduction in the amount of alkali in the blood is partly responsible for the breathlessness which promptly occurs on exertion at high altitudes, even in acclimatized persons.

As a result of the greater alkalinity of the blood the affinity of hemoglobin for oxygen is increased (see page 633) and the blood can therefore carry a larger amount of oxygen to the tissues even without any increase in the amount of

hemoglobin present. But there is also an increase in the number of erythrocytes in circulation; this polycythemia is brought about first by contraction of the spleen,* subsequently it is added to and maintained by augmented activity of the bone marrow (Barcroft[15]).

Fig. 270 is a graphic presentation of the data obtained by the expedition led by Barcroft to the Andes in Peru. The altitude was 14,200 feet and the barometric pressure was 458 mm., which is about 60 per cent of the pressure at sea level (760 mm.).

The *circulation* of the acclimatized person is practically normal when no strain is put upon it, but its capacity for meeting a demand for increased blood flow is reduced. The members of Barcroft's party had the same pulse rates under basal conditions, i.e., when just awakened from sleep, when residing at high altitude and at sea level, but even the slight exertion of sitting was enough to maintain some acceleration of the heart at the higher altitude.[15] The amount of exercise required to produce a given acceleration of the pulse of an individual acclimatized to 14,200 feet was about two-thirds that required at sea level. From data supplied to him by the 1924 expedition to Mt. Everest, Barcroft concludes that the pulse may remain normal during rest up to an altitude of 16,500 feet, while above that level persistent acceleration occurs. The Everest party noted pulse rates of 160 to 180 per minute while climbing in the neighborhood of 27,000 to 28,000 feet. All the members who went above 27,000 feet had dilated hearts. These were carefully selected, healthy, trained subjects. There can be no doubt that life at high altitudes entails a strain on the heart even after acclimatization. Cardiac depression and failure are prominent among the dangers of life at high altitudes.

Acclimatization is not equally effective in all persons. Individuals whose breathing increases in depth are better off than those in whom the rate is affected predominantly. This fact is illustrated by the following figures:

	ML. PER RESPIRATION	NO. OF RESPIRATIONS PER MINUTE	HEIGHT IN METERS AT WHICH SYMPTOMS OCCURRED
Subject 1	270	20	3300
Subject 2	440	14	6000
Subject 3	700	8	6500

(After Halliburton)

In Barcroft's party those in whom oxygen passed through the alveolar membranes at the most rapid rate became most completely acclimatized, but the diffusion rate of oxygen did not increase at the high altitude in any of the subjects. The arterial blood was about 85 per cent saturated with oxygen in these men instead of the normal 95 per cent, and samples of blood drawn directly from an artery had a distinct bluish color. *There probably is no secretion of oxygen into the blood: the oxygen tension in the blood is never higher than that in the alveolar air.*

In persons who spend their entire lives at high altitudes the chest becomes permanently enlarged; these people look as though they had severe pulmonary emphysema, but their vital capacities are increased, not decreased as in emphysema. The decrease in vital capacity in emphysema is associated with oblitera-

*This is at least true of laboratory animals, such as the dog. It is doubtful whether the human spleen is capable of contracting to any effective extent, for smooth muscle is not found in its trabeculae or capsule.

tion of a considerable proportion of the pulmonary capillaries, but in the native dweller at high altitudes the size of the pulmonary capillary bed is not reduced; it may actually be increased by dilatation of these vessels (Talbot and Dill). These individuals are able to get more oxygen from the air into the blood than would otherwise be possible, first, because they can get a higher tension of oxygen in the alveoli at each breath, and second (if Talbot and Dill are correct), because the area over which the venous blood is exposed to the alveolar air is increased by dilatation of the alveolar capillaries. Their blood shows an increase in hemoglobin, in oxygen capacity, in number of erythrocytes, and in the proportion of cells to plasma (hematocrit). Table XXV gives pertinent data obtained by Talbot and Dill[156] in five natives who lived and worked at 17,500 feet in the Andes in Chile.

TABLE XXV

ARTERIAL BLOOD OF FIVE HEALTHY NATIVES AT 17,500 FEET

SUBJECT	O_2 CAPACITY ML. PER 100	O_2 SATURATION PER CENT	HEMATOCRIT PER CENT CELLS	ERYTHROCYTES MILLIONS PER C.MM.	WHITE BLOOD CELLS PER C.MM.
Ca	32.7	74.8	74.7	7.48	5,200
Al	29.2	78.3	62.2	6.85	7,400

Ba	30.7	70.2	73.0	7.09	6,500
He	34.2	67.6	81.8	9.10	5,000
Normal (sea level)	20.9	95	46	5.40	6,000

According to Hurtado[85] the erythrocytes of natives at an altitude of 14,890 feet are abnormally large, but each red cell contains less hemoglobin than at sea level; the surface over which the hemoglobin is exposed for the gas exchange in the lungs and tissues is therefore unusually great, and this may be one of the most important factors in complete acclimatization. He found, in increased resistance of such blood to hypotonic hemolysis and in the presence of young forms (including reticulocytes) among the cells, evidence of continued activity of the hematopoietic system. Talbot and Dill also found reticulocytes, in numbers ranging from 0.4 to 3.4 per cent, among the erythrocytes in the blood of their subjects at 17,500 feet.

For further details of this interesting subject the reader is referred to the monographs by Haldane,[67] Barcroft,[15] and McFarland.[113] The chemical changes in the blood are discussed by Peters and Van Slyke.[126]

ANOXIA IN DISEASE

Anoxia is known to occur in diseases which affect *respiration* (pneumonia, emphysema, atelectasis), *circulation* (cardiac decompensation, congenital malformations, shock), or *hemoglobin* (anemia, carbon monoxide poisoning, methemoglobinemia). Histotoxic anoxia may occur in disease (other than in poisoning by cyanide, alcohol, or other narcotics), but there is as yet no evidence that such is the case.

In considering the anoxia of high altitudes we have seen that among the dangerous features in that condition are a blunting of the victim's perception of the usual warning signals such as pain, discomfort, and distress, and a diminished appreciation of the course of events. In anoxia due to

disease exactly the same situation is encountered, but here the decrease in cerebral acuity may mercifully diminish the patient's suffering and thus assist the physician. It is highly important, however, that the physician be not deceived by the euphoria produced by cerebral anoxia and that he remember that the underlying process is a disorganization of cell function which may have disastrous consequences if it is not checked. When the physician finds that a very ill person feels much better, he must at once determine whether this means actual improvement in the disease process or the onset of cerebral anoxia, for the procedures indicated are of course entirely different in the two cases.

Pneumonia produces anoxemia, primarily by reducing the aerating surface in the lungs. In addition, breathing becomes rapid and shallow and this contributes to the anoxemia because it makes alveolar ventilation less efficient; rapid, shallow breathing also means less complete rest for the respiratory neurons which are already suffering from anoxia. Furthermore, the circulation in the consolidated areas of the lungs is practically abolished while that through the normal parts is accelerated, and the flow of blood may be so rapid in the undiseased alveoli that the absorption of oxygen is incomplete. The greatest danger of anoxemia in pneumonia is produced by obstruction of bronchi leading to unconsolidated areas (Stadie[152]), i.e., by *bronchopneumonia,* in which the circulation in the alveoli of the affected parts is not obstructed.

In chronic pulmonary disease, such as chronic bronchitis, asthma and emphysema, anoxia is present because the blood is insufficiently oxygenated in the lungs. Acclimatization occurs as in the dweller at high altitudes and there may be little or no discomfort as long as the subject is at rest. Like the mountaineer, however, his tolerance for exertion is greatly diminished and his heart is subjected to a constant strain which is dangerously augmented when, as in exercise, his other tissues need more oxygen.

In *cardiac decompensation* anoxia occurs for two reasons: (1) anoxemia results from the presence of fluid in the finer air passages, and from the emphysema which frequently accompanies it; (2) stagnant anoxia is produced by sluggishness of the circulation in the capillaries.

In *anemia* the circulation is probably accelerated so as to compensate in part for the diminution in the amount of oxygen carried by each unit volume of blood. A larger compensating factor appears to be adaptation of the tissues to a lower oxygen tension during the slow development of the disease (Peters and Van Slyke[126]). It is probable that dilatation of blood vessels is a prominent factor in this adaptation.

In *poisoning by carbon monoxide* we encounter a form of anoxia that is particularly dangerous because this toxic gas not only appropriates some of the hemoglobin and thus deprives the body of that much of its ability to transport oxygen, but also because the presence of monoxide combined with part of the hemoglobin makes hemoglobin molecules which are not actually combined with monoxide "cling to oxygen with abnormal tenacity."[126] Both CO and O_2 combine with the iron of hemoglobin, but CO has an affinity 210 times that of O_2 for human hemoglobin, and when both gases are present the relative amounts taken up by the blood follow that proportion.

Poisoning by carbon monoxide is a serious and common condition. The gas is formed by incomplete combustion of carbon; it may be evolved from a coal fire which has insufficient draft, or from a charcoal brazier. Considerable amounts of it may be present in mines as a result of explosions or of spontaneous oxidation of coal. The sources of greatest importance to the average physician are the exhaust gases of motor cars and illuminating gas. The exhaust gas of a gasoline motor contains about 6 per cent of CO when the motor is fairly well adjusted and if the mixture is excessively rich in gasoline the proportion of CO will be higher than this. The illuminating gas manufactured in large cities usually contains about 30 to 40 per cent of CO, but the gas obtained as a by-product of the manufacture of coke contains only about 10 per cent CO and natural gas contains almost none.

Peculiarities of Poisoning by Carbon Monoxide.—The symptoms of monoxide poisoning are the usual symptoms of anoxia (page 677). One of the outstanding symptoms is headache—a severe, throbbing, frontal pain, worse in the recumbent than in the upright position, accompanied by nausea and associated with decreased mental capacity. Peters and Van Slyke[126] suggest that this symptom may be due to an increase in cerebrospinal fluid pressure

consequent upon increased permeability of cerebral capillaries as a result of anoxia. Respiration is not stimulated as much as in most other types of anoxia because in this case the oxygen tension of arterial blood is normal (until breathing becomes insufficient) and the receptors of the carotid bodies and aorta are therefore not stimulated even though the quantity of oxygen available to the tissues is greatly reduced.* Fainting and collapse occur frequently, and if the heart is at all weak it is likely to be seriously affected. *When half the hemoglobin is combined with monoxide the subject is on the verge of unconsciousness and collapse and will probably die if the exposure continues.* This is in striking contrast with the effects of reduction to the same extent in the amount of hemoglobin in anemia, for patients with a hemoglobin content of 50 per cent are in no immediate danger from anoxia. As already mentioned, this is because monoxide has a double effect on the ability of the blood to yield oxygen to the tissues: it reduces the amount of oxygen carried by the blood to the extent that the hemoglobin is combined with CO, while at the same time the presence of carboxyhemoglobin increases the firmness of the combination of oxygen with the rest of the hemoglobin, so that it gives up its oxygen to the tissues only at an excessively low oxygen tension. The second of these influences is added to the first and is almost as strong, so that the anoxia produced by monoxide is nearly twice as severe as would be expected from the reduction in the amount of oxyhemoglobin alone; *the oxygen tension of venous blood in monoxide poisoning is only about half that usually seen in blood containing the same amount of reduced hemoglobin.* Monoxide can exert a depressant effect on tissue oxidations because it interferes with the

Fig. 271.—Rate of absorption of carbon monoxide by the blood in persons exposed to concentrations up to 7 parts of CO in 10,000 of air for periods up to one hour, during rest (sitting) and for shorter periods of walking and working. (From Henderson, Haggard, Teague, Prince and Wunderlich: J. Indust. Hyg. 3: 79, 1921-22.)

activity of some of the enzymes concerned in the process (see Chapter XLVII), but this does not occur unless the concentration of CO is about one thousand times as great as that which suffices to cause death from combination of the gas with the hemoglobin; this effect of monoxide on tissue oxidations is an interesting fact, but it plays no part whatever in monoxide poisoning of higher animals or man.

*The reasons for this are as follows: (1) The amounts of CO in the inspired air which suffice to cause severe or fatal poisoning are of the order of 0.1 to 0.3 per cent (see Fig. 271), which are too small to produce a significant decrease in the partial pressure of oxygen in the alveolar air. (2) Monoxide does not directly interfere with the diffusion of oxygen across the pulmonary membranes, with the circulation in the alveolar capillaries, or with the solubility of oxygen in the blood. For these reasons the tension of oxygen in the arterial blood and the amount of oxygen carried by it in physical solution are not appreciably reduced in ordinary cases of monoxide poisoning as long as respiration continues to be adequate. (3) The hyperpnea of oxygen-lack is due mainly if not exclusively to reflexes aroused in the carotid and aortic bodies. These structures receive arterial blood directly through an artery arising from the occipital or external carotid and the aorta respectively. This blood is not exposed to any other active tissue before it reaches the chemoreceptors; the mass of tissue is so small that the amount of oxygen required to satisfy its needs must be very small, and the gas normally carried in physical solution in the blood is doubtless more than sufficient as long as the tension is not reduced. (4) When the amount of CO in the inspired air is high enough to reduce appreciably the partial pressure of oxygen in it (i.e., 5 per cent CO or more) the tension of oxygen in the arterial blood would of course be reduced, but in this respect CO is simply behaving like an inert gas and anoxic anoxia is superimposed upon the anemic anoxia that is the characteristic effect of this gas. Concentrations of this order are rarely encountered.

The severity of the symptoms depends on the amount of hemoglobin occupied by CO, and therefore on the tension of the gas in the alveolar air (also on the duration of the exposure—see below). *Since CO has an affinity 210 times that of O_2 for human hemoglobin a concentration of CO $\frac{1}{210}$ times that of O_2 in the inspired air would lead to 50 per cent saturation of hemoglobin with each gas; this would be accomplished by $\frac{20.9}{210} = 0.10$ per cent CO, or 10 parts per 10,000, which is dangerous to life if inhaled for a sufficient time.* Smaller concentrations (between 0.02 and 0.07 per cent) produce less characteristic effects, but prolonged exposure is liable to lead to symptoms of chronic anoxia (headache, nausea, weakness, etc.). Concentrations lower than 0.02 per cent (2 parts per 10,000) are harmless.

The duration of the exposure to monoxide is just as important as the tension of the gas in the inspired air unless the latter is so high as to produce instantaneous effects, which is rarely the case. Only about half the monoxide taken into the lungs is absorbed by the blood. Assuming 50 per cent saturation of hemoglobin by CO as the point at which collapse is likely to occur and absorption of half the CO in the inspired air, and knowing that the hemoglobin of an adult man can combine with about 1000 ml. of either CO or O_2 when fully saturated with either gas, we can estimate that the *average resting man is in danger of collapse when he has breathed enough air to contain about 1 liter of CO* (Peters and Van Slyke[126]). Henderson and his co-workers,[77] who made extensive experiments on men to ascertain the requirements for ventilation of the vehicular tunnel under the Hudson River between Jersey City and New York, came to the conclusion that *when the product (hours of exposure) × (concentration of CO in parts per 10,000 in the inspired air) = less than 6 in the resting subject there is no perceptible effect. When it reaches 9, headache and nausea appear. When it reaches 15 there is danger to life.* Thus exposure to 0.075 per cent CO for two hours, to 0.15 per cent for one hour, or to 0.3 per cent for one-half hour would be equally dangerous. The time of exposure is just as important as the concentration of CO in the air.

Exercise in the presence of monoxide is doubly dangerous, first because it increases the consumption of oxygen, and second because it leads to greater ventilation of the alveoli and therefore to more rapid absorption of the gas. A man who is exercising is in danger of collapse when his blood is only 30 per cent saturated with CO (compared with 50 per cent when at rest) and would therefore succumb to a CO concentration or a time of exposure about two-thirds that required to cause prostration of the resting subject. This is well shown in Fig. 271.

The after-effects of monoxide poisoning arise mainly from the central nervous system. One peculiar feature is that the symptoms may not come on until the subject has been removed from the noxious atmosphere and much of the poisonous gas has been eliminated from the body. An individual who has been poisoned by monoxide is not responsible for his actions; a man who had just been rescued from a mine shook hands with his rescuers and then knocked one of them down in resentment at the offer of further help. Collapse may occur several hours after the exposure, and there may be a prolonged period of mental aberration. Such individuals are unusually susceptible to respiratory diseases, and since their cooperation cannot be counted upon they must be watched and nursed carefully.

The treatment of acute monoxide poisoning follows the usual lines of resuscitation (page 667). Oxygen inhalation, with the addition of 5 to 7 per cent CO_2, is the most helpful procedure. *Chronic poisoning* with carbon monoxide is not generally recognized as a clinical entity, but it is possible that some vague symptoms, such as headache, nausea, and lassitude in workers in garages or foundries, or in children living in ill-ventilated quarters in which a gas stove is used, may be due to slow accumulation of the gas in the blood.

CHAPTER XLVI

THE EFFECTS OF BREATHING AIR UNDER INCREASED PRESSURE; AEROEMBOLISM; OXYGEN INHALATION; ARTIFICIAL RESPIRATION

CAISSON DISEASE

We have seen in Chapter XLV that when man breathes air under diminished pressure he develops a train of symptoms referable to the anoxemia which results from a decrease in the partial pressure of oxygen in the inspired air. When man exposes himself to air under *increased* pressure, another set of symptoms arise. These do not come on during the exposure to increased pressure but only afterward, when the victim has returned to more normal surroundings. They are ushered in and accompanied by severe pain and there is no acclimatization here as there is to low pressures. In these respects (as indeed in nearly all others) the physiological effects of exposure to excessive barometric pressures are quite different from those of exposure to subnormal pressures. The only outstanding similarity between the two is sudden collapse and death if the condition is extremely acute. Increased atmospheric pressures are encountered most frequently by divers and by workers in caissons; the symptoms are therefore widely known as "diver's palsy" and "caisson disease"; terms frequently used by the workers themselves are "the bends" and "the chokes." Recently, by reason of the advances in aeronautic engineering, occupants of aircraft have been exposed to precisely the same conditions because of the rapid rate of ascent of modern aircraft; for this the term "aeroembolism" has been suggested (see page 698). As we shall see when we come to inquire further into the symptoms, the underlying cause is the same in all these cases, i.e., embolization of blood vessels by bubbles of nitrogen which are liberated from solution in the body fluids by the reduction in tension of the gas in the blood. These emboli accumulate in the blood vessels because the rate at which nitrogen is liberated is faster than that at which the excess gas can be dissolved in the blood and eliminated in the lungs.

The *symptoms* are substantially the same no matter how the condition is brought about. Typically they begin with pains in the muscles and joints (usually the knees); the arthralgia may be due to distention of the joint by gas (which has actually been demonstrated roentgenologically in the knees of a victim of caisson disease[64]). Then come symptoms referable to emboli in the peripheral nerves, first sensory disturbances (formication, pruritus, localized sensations of heat and cold), then motor involvement (weakness, paralysis). Skin eruptions of the urticarial or herpetic type may occur at a rather early stage in the disease as encountered in aviators; these lesions apparently have a neurogenic origin. Involvement of the central nervous system may lead to vertigo, pains in the ears, and deafness, vomiting, breathlessness, convulsions, and coma. In severe cases there may be only a brief interval between the initial arthralgia and motor paralysis; the subject then becomes helpless and falls, and he is likely also to lose consciousness. Respiration becomes labored, the face is cyanotic, the pulse is almost imperceptible, and unless the victim is

quickly recompressed death is likely to ensue. In the milder cases recovery is usual but arthralgia and myalgia may persist for a considerable time.

Autopsies of persons dead of caisson disease have shown, as a rule, intense congestion of the viscera, hemorrhages into the spinal cord and brain, subcutaneous emphysema, and ecchymoses in the pleura and pericardium. In some cases interlobular emphysema of the lungs and laceration of the spinal cord and brain have been noted. In animals gas emboli are found in the blood vessels and the heart may be filled with froth instead of blood; this explains the weakness of the pulse in severe cases.

The Cause of the Symptoms.—For many years it has been known among divers and caissoniers that "on ne paie qu'en sortant,"[67] i.e., that the danger arises, not from the compression, but from the subsequent decompression. This was first established by the work of Paul Bert, which has been repeatedly confirmed (see Haldane[67]). The recent discovery that the disease can appear in its most severe form in an individual who has never been exposed to a pressure higher than that of the normal atmosphere, but who is decompressed by rapid ascent in an airplane, shows that the preliminary sojourn at the increased pressure is not essential. The aviator suffers because he is decompressed from a normal barometric pressure to a subnormal one, whereas the diver or caissonier shows identical effects on being decompressed from a hypernormal pressure to a normal one. Behnke[23] points out that an aviator ascending from sea level to an altitude of about 33,000 feet is being subjected to exactly the same degree of decompression as a diver coming to the surface after a sojourn at a depth of 100 feet in sea water; in the former case decompression occurs from the pressure of one atmosphere to one-quarter that value (see Table XXIV, page 679), while in the latter it occurs from a total pressure of four atmospheres to that of one.

The diver and caissonier are unavoidably exposed to increased pressure, the former because the air pressure inside his suit must be as high as that of the surrounding water or he would be unable to breathe, the latter because water is kept from flooding the excavation only by raising the pressure inside the latter. Every 33 feet of sea water (34 feet of fresh water) means an additional pressure of one atmosphere. The blood of the man exposed to an increased pressure takes up the gases of the atmosphere in direct proportion to their partial pressures (Henry's Law—page 616); at a pressure of two atmospheres, twice as much gas will be dissolved as at one. The only gases that we need consider are oxygen and nitrogen, since carbon dioxide is not (or should not be) allowed to accumulate because the resulting breathlessness will greatly impede the performance of work and CO_2 may (when compressed) cause stupefaction (i.e., narcosis). The excess oxygen is used by the tissues, but the body can do nothing with the excess nitrogen except dissolve it until the tension of the gas in the tissues, tissue fluids, and blood is again equal to that in the atmosphere (i.e., until saturation has occurred); then the number of gas molecules leaving the blood in the lungs is again equal to the number entering it (i.e., a new equilibrium is struck at a higher tension, involving the movement of more gas molecules in proportion to the increased pressure). Since nitrogen is an indifferent gas, no abnormalities result from the presence of increased amounts of it as long as it remains dissolved.

The peculiar dangers in this situation arise from two facts: (1) nitrogen diffuses relatively slowly through living membranes; (2) it is about five times as soluble in fat as in water,[160] and since fatty tissues are also rather poorly vascularized, equilibrium between blood and fat with respect to the tension of nitrogen is slowly attained in either direction. Consequently, it takes considerable time for the body to absorb its full quota of nitrogen at a given atmospheric pressure and to eliminate the excess when decompression occurs. The blood in man constitutes one-twentieth of the body weight, so that if the tissues were all liquid, they would dissolve 20 times as much nitrogen as the blood. Because of their fat content, however, the tissues take up more than this, the amount in

the average man being about 35 times as much as the blood. Since a complete round of the circulation takes about one minute, the body, when suddenly exposed to an increased pressure, will be about $\frac{1}{35}$ saturated with nitrogen in one minute, another $\frac{1}{35}$ in two minutes, and so on. At this rate the body would be about 22 per cent saturated with nitrogen in five minutes and about half saturated in twenty-five minutes, but it would take about two hours for saturation to be complete, even if the blood were evenly distributed throughout the body. Because of the poor vascularization of fatty tissues these will lag behind the others and complete saturation will be further delayed.

The results of sudden decompression of the body are entirely comparable with those of sudden removal of the stopper from a bottle of carbonated fluid: the gas, previously dissolved at a high pressure and entirely invisible, comes out of solution in gross bubbles and effervescence occurs. To decompress without danger involves the counterpart of making a tiny hole in the stopper: the excess gas escapes gradually and no effervescence results. Other things being equal, it takes about as many minutes to desaturate as to saturate. Both processes can be accelerated by exercising, and for two reasons: first, because the circulation rate and alveolar ventilation are both increased; and second, because the blood flow through the tissues is accelerated by the vasodilatation attendant on muscular exercise. This fact has long been utilized by divers and caissoniers, who can hasten materially the rate of decompression by exercising or working during the process. Perhaps it could also be utilized by the occupants of a rapidly ascending aircraft.

When decompression is rapid, the excess nitrogen dissolved in the blood at the higher pressure comes out of solution and gas emboli may be formed at once in the pulmonary capillaries (hence the asphyxial symptoms). Because of the lowered pressure of nitrogen in the blood, bubbles of the gas also appear in the tissues, first in those with the best blood supply, later in those with poorer vascularization. Myalgias and epigastric pain are probably due to embolization of blood vessels in the muscles and gastrointestinal tract, the arthralgias to distention of the joints with gas liberated into them, and the nervous symptoms to gas emboli in vessels supplying the central and peripheral nervous systems. Once these emboli have appeared they can be gotten rid of rapidly only by bringing them back into solution by raising the atmospheric pressure again.

The Prevention of the Symptoms.—From what has been said about the cause of these symptoms it follows that, if they are to be prevented, decompression must take place so gradually that the excess nitrogen can be eliminated from the body rapidly enough to prevent the appearance of gross bubbles of nitrogen in the capillaries. The time required will depend both on the extent of the original compression (in a diver or caisson worker) and on the duration of the exposure. In the *aviator* the extent of the compression is of course always the same (i.e., equilibrium at a normal barometric pressure); the important factors here are the rate and extent of decompression. Experience has led to the establishment of certain rules for the decompression of divers and caisson workers.[67, 83] The corresponding situation in aviators is too recent to permit similar treatment (see Armstrong[7]). In any case, once serious symptoms have appeared, immediate recompression is indicated.

Recently helium has been substituted for nitrogen in the air used to supply divers in the U. S. Navy, and this has made possible deeper dives, longer sojourn under water, and more rapid ascent without dangerous symptoms. The reason for this is that helium is only about one-half as soluble as nitrogen in body tissues while at the same time it diffuses about twice as rapidly as nitrogen through living membranes. Consequently, the amount of helium taken up in the diver's body in a given time and at a given pressure would be considerably less than the amount of nitrogen absorbed under the same conditions; the rate at which the excess helium is eliminated from the body when decompression takes place is also considerably more rapid than would be the case in a nitrogen-oxygen atmosphere. The fact that helium is so much lighter than nitrogen that a helium-oxygen atmosphere can be moved with less effort and will more

readily pass a partial respiratory obstruction plays no part in this particular use of the gas; it is important in the relief of asthma, laryngeal obstruction, tracheal stenosis, etc. (Barach[11]).

AEROEMBOLISM

If it is true that the deleterious effects of exposure to air under increased pressure are due to obstruction of capillaries by bubbles of nitrogen which are no longer held in solution when the environmental pressure is rapidly reduced from an abnormally high level to that of the normal atmosphere, it follows that similar effects should be elicited by the sudden reduction in the environmental pressure encountered during rapid ascent in an airplane. It is now well known[8, 155] that this is the case and Armstrong[8] has suggested the term *aeroembolism* to designate the pathological entity thus brought about. The symptoms are identical with those of caisson disease: pain in the joints usually is the first sign, followed by paresthesias (formication, pruritus, or localized sensations of heat or cold) and these by symptoms referable to gas emboli in peripheral nerves, or in the central nervous system (paralyses, convulsions, coma). Skin eruptions of the urticarial or herpetic type may occur at a rather early stage.

The *cause of the symptoms* is obviously occlusion of end-arteries by bubbles of nitrogen, the rate of diminution in the environmental pressure having been too rapid to permit the gas to be eliminated by the lungs as rapidly as it comes out of solution in the body fluids. According to Armstrong, these effects are not likely to arise at any level lower than 30,000 feet (226 mm. barometric pressure) no matter how rapid the ascent; at or above that level, however, symptoms may ensue even when the rate of climb is less than 200 feet per minute. Different individuals vary greatly in their susceptibility to this condition but here, as in divers and caissoniers, fat subjects are generally more susceptible than lean ones, and for the same reason in both cases, viz., nitrogen is much more soluble in fat than in water and desaturation of fatty tissues is a very slow process because of their poor blood supply. In some persons the symptoms come on at an altitude considerably below 30,000 feet. As in caisson disease, the symptoms begin only after the exposure has lasted for some time; this delay tends to be greater with slower rates of ascent than with more rapid ones.

The *treatment of aeroembolism* is obviously recompression, which is easily done simply by descending to a lower altitude. This condition must not be confused with the anoxia of high altitudes although some of the outstanding effects (especially those on the central nervous system) are very similar. Oxygen inhalation will not remedy aeroembolism once it is established; it will aid in ridding the body of nitrogen because it lowers the tension of the latter gas in the inspired air, but existing gas emboli can be gotten rid of rapidly only by redissolving them, and this necessitates a return to the pressure at which they go into solution. Oxygen inhalation would prevent aeroembolism provided that sufficient time is given for desaturation with nitrogen to occur; if the ascent is to be rapid (and most of the modern military aircraft can climb much faster than is necessary to lead to aeroembolism) it will, however, be necessary for the inhalation to begin some time before the ascent. Because 30,000 feet appears to be a critical level for the occurrence of aeroembolism in many persons it is probably inadvisable for commercial aircraft to operate

as high as this even with sealed cabins; in the event of sudden leakage or failure of the compressing mechanism oxygen inhalations could be used to forestall fulminating anoxia, but they would not prevent severe or fatal effects from the gas emboli resulting from rapid decompression. Helium-oxygen mixtures could be used to prevent aeroembolism in aviators as well as "the bends" in rapidly decompressed divers, but this procedure, while entirely practical for diving because special vessels are outfitted for the purpose, is impractical in aircraft because it would involve additional equipment and offer slight if any advantages over inhalation of oxygen alone.

Since the boiling point of water is reduced by lowering the barometric pressure to which it is exposed, an altitude must exist at which the body fluids would boil at body temperature. Theoretically this should occur at an altitude of 63,000 feet, for here the barometric pressure (47 mm. Hg) is equal to the water vapor tension of the body fluids (page 548). Armstrong and his colleagues[8] have actually seen this phenomenon taking place in a transparent cell through which an animal's blood was passed. No changes were visible until an altitude of 55,000 feet was reached, when the film of blood suddenly assumed a grayish appearance, probably because of the liberation of minute bubbles of gas or vapor. At 58,000 feet macroscopic bubbles appeared, at 61,000 these were more numerous, and at 63,000 very suddenly all of the fluid blood was replaced by a mass of bubbles. This phenomenon is interesting, but since the occupants of an open-cockpit plane would die from anoxia at a considerably lower altitude even if they were breathing 100 per cent oxygen (page 703) the practical importance is not great.

THE THERAPEUTIC VALUE OF OXYGEN

When oxygen is properly administered in certain types of pulmonary disease before the patient has become moribund, very great benefit may result from the treatment, and as far as can be told a fatal termination is often averted.

Theoretical Considerations.—In order to understand the physiological principles involved in this treatment, it is important to remember that although more than fifty times as much oxygen is combined with hemoglobin as is in simple solution in the blood plasma, yet it is the latter which really diffuses into the tissues. The pressure of oxygen in the plasma, in other words, the diffusion pressure of oxygen, is the determining factor in causing it to permeate the tissues, and whenever this pressure begins to fall under normal conditions, more is added to the plasma by dissociation from the oxyhemoglobin of the corpuscles. The plasma retails the oxygen to the tissues, and the corpuscles are the wholesale warehouses from which the plasma replenishes its stock. The unloading of oxygen from the oxyhemoglobin to the plasma is assisted by various chemical changes that take place while the blood is in the capillaries. From these considerations it follows that an efficient supply of oxygen to the tissues could be maintained without any hemoglobin if we were to put an excess of the gas into simple solution in the plasma; that is, if enough were forced into solution in the plasma in the lungs so that the tissue requirements could be met without any local addition from oxyhemoglobin. Two experiments may be quoted to show that it is possible to fulfill these conditions:

1. After replacing all the blood from the blood vessels of a frog by artificial plasma (Ringer's solution) the animal can be kept alive for days in a vessel

containing pure oxygen (i.e., five times the amount present in air) and during this time the O_2 consumption and CO_2 production are practically the same as under normal conditions.

2. Small mammals (mice) exposed to air containing more than 0.5 per cent of carbon monoxide (contained in coal gas) soon become moribund, because the oxygen carrying power of the hemoglobin is entirely abolished by the formation of carboxyhemoglobin. If the animals are now transferred to pure oxygen under two atmospheres pressure (i.e., ten times the amount in air) they quickly recover.

Both experiments show clearly that if we succeed in getting sufficient oxygen into simple solution in the plasma, the oxyhemoglobin is not necessary to supply the tissues with this gas.

One of the greatest uses of oxygen inhalation is in the *treatment of poisoning by carbon monoxide.* In this condition the monoxide competes with oxygen for combination with the iron of the hemoglobin molecule and the affinity of the former is about 210 times that of the latter. Yet it is a quantitative relationship, and as the tension of oxygen is increased this gas displaces monoxide. The addition of CO_2 to the inspired mixture assists in turning monoxide out of the blood for two reasons: (1) The deeper breathing leads to an increase in the tension of oxygen in the alveoli while at the same time the monoxide is more thoroughly removed; (2) CO_2 affects the dissociation curve of carboxyhemoglobin in the same way as it does that of oxyhemoglobin (page 632); therefore at a given tension of monoxide in the alveolar air less is combined with hemoglobin when the CO_2 tension is increased. In addition, the inhalation of pure oxygen leads to the uptake of more oxygen in physical solution (2 ml. per 100 from an atmosphere consisting entirely of oxygen instead of 0.3 ml. from the normal atmosphere), and that fraction of hemoglobin which normally passes through the lungs unoxygenated (equivalent to about 1 ml. of oxygen per 100 ml. of blood) is oxygenated; thus the blood takes up an additional load of about 3 ml. of oxygen per 100 in forms readily available for utilization by the tissues and the acute symptoms of anoxia can therefore be immediately alleviated by inhalation of pure oxygen even without displacement of CO from its combination with hemoglobin.

In pulmonary edema, in "gassed" cases, in bronchitis, and in decompensated cardiac cases, oxygen is of undoubted value, when it is properly administered. Many cases of *pneumonia* are also benefited by such treatment, but there are others in which the heart is so profoundly affected by toxic substances that oxygen may perhaps be of little use. Evidence of this benefit is afforded by the easier and deeper breathing, the slowing of the pulse, the disappearance of cyanosis and the greater ease and comfort experienced by the patient. Not only do these effects persist as long as the gas is given, and thereby serve to tide over a crisis and permit the natural defensive agencies of the body more successfully to combat the abnormal condition, but they often outlast the administration. In severe angina pectoris associated with coronary occlusion oxygen inhalation may bring relief from pain because it ameliorates the anoxia of heart muscle that was responsible for the pain.[26]

Quantitative evidence that in pneumonia the arterial blood is improperly saturated with oxygen in proportion to the degree of cyanosis, and therefore of the condition of the patient, has been furnished by Stadie.[152] In a normal person the arterial blood carries 95 per cent of its full load of oxygen, but in pneumonia only a little over 80 per cent. Meakins[114]

has confirmed these findings, and has added most important observations on the effect of oxygen inhalations by the Haldane method. In a case of pneumonia the oxygen unsaturation on the eighth day of the disease was 17.9 per cent. After two hours of oxygen treatment (at a rate of delivery of 2.5 liters O_2 per minute) the unsaturation percentage fell to 9.08, and after 18 hours (at 1 liter per minute) it was 9.0. The O_2 was then discontinued and in 4 hours the unsaturation percentage had risen to 15.5. It fell subsequently to 3.05 after 24 hours, during which 3 liters O_2 per minute was administered. Shortly after this the crisis occurred. Similar results were obtained in a case of chronic bronchitis, and even in normal men it was found that inspiration of 3 liters of O_2 per minute for 100 minutes changed the arterial blood from 4.4 per cent unsaturation to 1.87 per cent.

To explain exactly how the oxygen acts in this group of cases several possibilities must be considered. In the first place we must suppose that the respiratory membrane has become greatly reduced in extent because the alveoli in certain parts of the lungs have become more or less filled with fluid or exudate. Under these circumstances the blood circulating in the vessels of the affected portion of lung cannot be reached by a sufficient amount of oxygen to saturate its hemoglobin fully, because there is an inadequate diffusion pressure of oxygen to penetrate the thick layer of fluid between the alveolar air and blood. When the exudation completely fills the alveoli the blood ceases to circulate through the capillaries of the affected part, so that all the blood is passing through the capillaries of healthy parts. This explains why the arterial blood may remain bright red in color in cases where there is complete consolidation or collapse of considerable areas of lung. So long as the hemoglobin is not fully saturated the tension of oxygen in the plasma must become very low and little can be available for the tissues when the blood arrives in their capillaries. When excess oxygen is breathed, the amount which goes into solution in the fluid will become proportionately raised so that there will be a much better chance for a sufficient amount to reach the plasma, so as to saturate the hemoglobin and create a proper tension in the plasma.

In pneumonia the blood which leaves the lungs as a whole is a mixture of blood, still more or less venous from the blocked portions, and of arterial blood from the healthy portions, and it may be considered that the mixture is just on the border line of being adequate to supply the oxygen requirements of the tissues and nerve centers—otherwise the individual could not live. A very small improvement in the oxygen supply will therefore suffice to turn the tide. It is possible that the additional oxygen may reach the blood by diffusion through the fluid that has collected in the alveoli. By increasing the pressure of oxygen in the inspired air, more will become dissolved in the fluid (by Henry's Law, page 616) so that the pressure gradient from air to blood through the fluid will become steeper. But another factor must be considered; namely, that the increased partial pressure in the healthy alveoli has caused more O_2 to go into simple solution in the plasma of the blood circulating in these portions, and although this cannot cause the hemoglobin of the blood to carry away any greater load of the gas, yet when this blood is mixed with that from the pathological lobes, the dissolved oxygen will assist in bringing the hemoglobin up to its proper degree of saturation with oxygen.

It has been imagined by some that it is useless to give oxygen because the dissociation curve of the blood at varying pressures of the gas (page 632) shows that even after reducing the partial pressure of oxygen to one-half that obtaining in normal alveolar air, the blood still takes up 80 per cent of its full load. It is argued that it is therefore futile to attempt to increase the oxygen carried by the blood by raising the partial pressure in the air which is inspired into the still healthy alveoli. From what has been said above, however, it is clear that this viewpoint does not take into account two important effects which follow when the partial pressure of the oxygen is increased; namely, that under this condition oxygen diffuses much more rapidly through the fluid in the pathological

portions of the lung, and that at the same time more goes into simple solution in the plasma that is circulating in the healthy portions.

Principles in Method of Administration.—The success of any treatment with oxygen must depend on several factors, the most important of which are: (1) to get as much of the gas into the alveoli as possible; (2) to start the treatment early before irreparable damage has been done because of anoxemia; and (3) to maintain the administration until cyanosis disappears. With regard to the first of these factors, it has sometimes been thought that there is an element of danger in giving too much oxygen. This depends on the observation made by several investigators that animals that have been caused to live in more than one atmosphere of the pure gas for some time develop symptoms of pulmonary irritation, which may lead to pneumonia. By the best methods of administration, however, a concentration of not more than 85 per cent of oxygen can be attained in the alveoli. Karsner has shown that under such conditions there is no danger in inhaling pure oxygen, even for long periods of time.

The importance of early administration is evident when we realize that injury to the nerve centers and the tissues from insufficient oxygen usually develops insidiously, and that once started the damage must lead to a progressive deterioration of the vital functions of the body. The respiratory center is among the first to suffer from the anoxemia. The result is shallow and rapid breathing. Such breathing does not, however, properly ventilate the alveoli, so that the anoxemia becomes aggravated, and a vicious respiratory circle becomes established. The defensive agencies of the body against toxins and bacteria are also depressed by the anoxemia so that resistance to the further progress of the disease is lessened. It is also possible that prolonged oxygen deficiency, or the appearance of some toxic substance in the blood as a result of anoxia, renders the hemoglobin less capable of carrying oxygen by changing some of it into methemoglobin. It is at least significant that this compound is formed in animals after massive injections of streptococci (Peabody[123]). The maintenance of an adequate tension of oxygen in the plasma by administration of oxygen may retard the development of toxic substances.

For similar reasons, the administration should be maintained until all signs of deficient oxidation are removed, the best index of this being the color of the face. So long as there is any anoxemia the face has a characteristic pale ashen hue, different from that of ordinary capillary congestion.

Methods of Administration.—It may be said at once that the older clinical practice of placing a funnel connected with an oxygen tank in front of the patient's face is seldom of any use. At the rate at which the oxygen is usually applied by this method, it is inconceivable that any measurable increase in the percentage of oxygen in the alveolar air could be attained, and if enough gas were turned on to have some influence, the waste due to diffusion into the air would be tremendous.

Where no special apparatus is obtainable for the administration, the best method is to pass a wide gum elastic catheter into one nostril, through which the gas, after bubbling through water in a flask, is passed as rapidly as is comfortable for the patient. The method is rendered much more efficient if the open nostril is closed by the attendant during each inspiratory act. It has been found that by this latter procedure the concentration of oxygen in the alveolar air can be raised to 35 per cent. With the opposite nostril open, this percentage was much less. A smaller catheter passed through one nostril into the nasopharynx is even more effective.

Of the special appliances now available, the most satisfactory is the face mask devised by Boothby and his colleagues and commonly known as the BLB mask.[102] This is also the most effective method for administering oxygen to occupants of aircraft. The oxygen content of the inspired air in this apparatus can be raised to 80-100 per cent. It is, however, rather uncomfortable to use for long periods. The same workers[27] have also devised a small, self-contained inhaler and source of oxygen for use by aviators in the event of sudden failure of the plane's oxygen supply, or of the necessity to "bail out" at a high altitude. They point out that under either of these conditions, without any emergency supply of oxygen, it would be necessary to plunge to a level of breathable air (18,000-20,000 feet) in about one and one-half minute or consciousness would be lost; if the plane was at 35,000 feet when this happened, the strain of such a plunge on machine or man would be terrific and perhaps unbearable.

The various forms of oxygen tents cannot raise the oxygen content of the inspired air much above 40-60 per cent.

Administration of oxygen through a tracheal catheter has already been mentioned (page 672); by this means anoxemia can be prevented in the absence of any respiratory movements. It is also said to be effective in newborn infants even though the lungs have never been expanded (page 674).

Limitations of Oxygen in Aviation.—At first glance it might seem that the height at which safe flight is possible for subjects breathing pure oxygen is limited only by the capacity of the aircraft. Unfortunately this is not the case, and since the reasons are not yet well known, it is proper to inquire briefly into them at this time. The reader who is particularly interested will find the subject discussed fully by Armstrong.[8]

As far as respiration is concerned, the main physiological limitations to ascent in aircraft are: (1) the danger of aeroembolism consequent upon rapid ascent, and (2) the danger of anoxia resulting from reduction in the barometric pressure until the tension of oxygen in the inspired air becomes too small to secure adequate oxygenation of the blood in the lungs; this can occur even

Fig. 272.—Oxygen, carbon dioxide, and nitrogen tensions in alveolar air and oxygen saturation of arterial blood while breathing pure oxygen at altitudes between 24,000 and 40,000 feet. Average values obtained on healthy young subjects. (From Armstrong: Principles and Practice of Aviation Medicine, Baltimore, 1939, Williams and Wilkins.)

though the inspired atmosphere consists entirely of oxygen. The first of these has already been considered (page 698); inhalation of oxygen will not obviate aeroembolism unless begun some time before the ascent. The second has been investigated by Armstrong and Heim,[8] with results that are shown in Fig. 272.

These subjects were studied while breathing practically 100 per cent oxygen at altitudes ranging from 24,000 to 40,000 feet. At the former altitude the alveolar air showed the following average tensions: oxygen 195 mm., nitrogen 5 mm., carbon dioxide 36 mm.; the arterial blood was a little closer to complete saturation with oxygen at the 195 mm. tension than it was in the same subjects breathing ordinary air at sea level. Both alveolar oxygen tension and arterial oxygen saturation fell steadily as the altitude increased, and at 33,000 feet the former reached 105 mm. (which is practically a normal value for the alveolar oxygen tension at sea level). Arterial oxygen saturation began to fall below its sea level value at about 27,000 feet, and at 33,000 feet it was about 94.5 per cent as compared with a normal of 97; the reason for this fall in spite of a supposedly normal alveolar oxygen tension is as yet unknown.

At 40,000 feet alveolar oxygen tension had fallen to 62 mm. and arterial saturation to 88 per cent (average); the latter corresponds approximately with the value found when breathing ordinary air at 12,000 feet. Some of these individuals did not show a significant hyperpnea as anoxemia developed, and in these the arterial oxygen saturation fell to 83 per cent at 40,000 feet; this is about the same as that found when air is breathed at 15,000 feet (see Table XXIV, page 679).

"From the practical standpoint, taking into consideration not only our ability to create normal concentrations of oxygen in the lungs, but also the limitations of our present oxygen equipment, the frailties of human nature, and the consequences of a loss of oxygen supply at high altitude, it is believed that it cannot be considered a safe practice to fly above 20,000 feet where the safety of the flight depends on the inhalation of oxygen. Flights at 25,000 feet must be considered as definitely hazardous and 30,000 feet should be the absolute allowable limit of high flying in any except the most unusual circumstances. In no instance should anyone ever be allowed to fly above 40,000 feet" (Armstrong,[8] p. 321). The absolute ceiling to flight with oxygen (but without compression of the inspired gas) is reached when the barometric pressure equals the sum of the exhaled water vapor (tension 47 mm.) and carbon dioxide (tension 40 mm.); this is encountered at an altitude of about 50,000 feet (Table XXIV). At this height the alveolar oxygen tension would be zero even if pure oxygen were being inhaled, for the lungs would be filled with water vapor and carbon dioxide (total tension 87 mm.) and the pressure exerted on the inspired oxygen (87 mm.) could not force it into the deeper air passages. It is true that the carbon dioxide tension should be reduced below the value that is normal at sea level (40 mm.) by the increased respiration characteristic of high altitudes and this would raise the absolute ceiling somewhat; yet even if there were no carbon dioxide whatever in the alveoli (which could not occur) the exhaled water vapor alone, as we have seen on page 699, would fill the lungs completely at an altitude of a little less than 63,000 feet. Armstrong[8] found that rabbits exposed while breathing pure oxygen to altitudes of 43,000, 45,000, 47,000 and 50,000 feet died from anoxia in 120, 32, 7, and 3 minutes respectively.

These limitations can of course be circumvented by means of a sealed-cabin airplane in which the occupants breathe air that is maintained at a pressure approaching the normal at sea level. In so doing, however, another hazard—that of aeroembolism—is encountered at altitudes higher than 30,000 feet (page 698).

Oxygen Poisoning.—Since it is now possible by means of suitable equipment (such as the BLB mask[102]) to inhale practically 100 per cent oxygen for indefinite periods of time, the possibility of toxic effects from this procedure becames a matter of considerable importance. Recent investigations indicate that inhalation of pure oxygen by normal persons at sea level should not be continued for longer periods than six to seven hours because, after that time, symptoms suggesting pulmonary irritation (substernal soreness aggravated by a deep inspiration) and hyperactivity of the parasympathetic nervous system (flushing of the face, nausea, or actual vomiting) are apt to appear;[23] in one case repeated vomiting and actual bronchopneumonia ensued.[22] Pure oxygen given under increased pressure produces epileptiform convulsions; at a pressure of 4 atmospheres these come on in about forty-five minutes and Behnke[23] has suggested that the convulsions so produced might be tried in the treatment of

mental diseases. The cause of these symptoms is at present uncertain; direct irritation of the respiratory passages and lungs probably accounts for the pulmonary symptoms, but the other manifestations remain unexplained. The convulsions have been attributed to accumulation of carbon dioxide in nerve cells because, since the needs of the tissues for oxygen are met by the amounts physically dissolved in the plasma at such tensions as these, oxyhemoglobin is not reduced and alkali is not made available to transport carbon dioxide away from the tissues. If this explanation is correct, the CO_2 tension of the venous blood should be higher than normal under such circumstances, but this apparently is not the case; furthermore, there is abundant evidence to indicate that carbon dioxide in excessive amounts is narcotic to nerve cells but little or none to justify the belief that it is a convulsant.

The significance of these facts for the average physician is probably not very great for several reasons: first, there is general agreement that inhalation of oxygen in concentrations lower than 60 per cent is entirely harmless under any circumstances, and as the gas is usually given this concentration is not likely to be exceeded; second, when used by aviators the inhalation would not begin until an altitude was reached at which even 100 per cent oxygen would produce a tension in the blood little if at all above that normally existing while breathing air at sea level; third, in patients in whom inhalation of pure oxygen is indicated (such as cases of severe poisoning by carbon monoxide, coronary occlusion with severe shock, pneumonia, or acute pulmonary edema) the risk of doing harm by means of the oxygen is trivial compared with the damage being done by anoxia. It is not unlikely that patients with severe anoxia are less likely to be poisoned by oxygen than are normal subjects.

ARTIFICIAL RESPIRATION

By far the most satisfactory method to use in the resuscitation of asphyxiated persons is that known as Schäfer's. The patient is placed in the prone position with the arms extended and the head turned to one side. The mouth and throat are cleared of any foreign material and the tongue is pulled forward. The operator kneels astride the patient and places his open hands over the lower ribs with his arms extended. He then leans forward so as to compress the abdomen and force the diaphragm upward, maintaining the pressure for about two seconds, and follows this by leaning back to release the pressure, again for about two seconds. This is kept up until natural breathing returns or until it becomes certain that success is impossible. It has been shown by measurement of the air entering and leaving the lungs that this is by far the most efficient method of resuscitation, but its efficacy depends on seeing (1) that the pressure is applied to the lower ribs and (2) that the rhythm is not made too rapid.

When available, inhalation through a mask applied over the patient's face of oxygen containing 7 per cent CO_2 is of very great advantage. The oxygen tension is thereby greatly raised in the blood, improving the heart's action, and the CO_2 acts as a stimulus to the respiratory center. In CO-poisoning the use of O_2 and CO_2 is especially important. In all cases the patient must, of course, be kept warm by hot water bottles, etc.

The most efficient method of artificial respiration (and the only one which can be kept in operation for long periods of time in patients who are unable to

breathe) is the Drinker respirator.[50] This is a metal chamber in which the body of the patient is placed while the head remains outside; a rubber collar about the neck provides an air-tight seal. By means of mechanical pumps air can be rhythmically sucked out of the chamber and both the rate and the intensity of the process can be regulated. Thus the chest is expanded because the pressure on its surface is reduced; the head is outside the chamber and air under atmospheric pressure enters the lungs for the same reason that it does when the subject breathes naturally; i.e., because the pressure on the pleural surfaces of the lungs is lower than atmospheric. The expiratory phase of breathing can be allowed to occur passively or it can be made active—the latter by pumping air under positive pressure into the chamber during the expiratory part of the cycle. This apparatus is available in a number of large hospitals in the United States and it has proved to be extremely satisfactory for both acute and chronic cases.

Methods of artificial respiration which depend upon blowing air under positive pressure into the lungs have fallen into disrepute. One reason for this is that if the blast of air (or oxygen) is sufficient to distend the chest it may at the same time press upon the walls of the alveoli with enough force to obstruct the flow of blood in the pulmonary capillaries. The ventilation of the alveoli is accomplished with little or no change in their size (page 618) and therefore without interference with the pulmonary circulation, but the introduction of positive pressure in the respiratory passages alters this situation in a most dangerous way. The manual methods (such as that of Schäfer) and the Drinker apparatus obviate this danger. Yet the method of intratracheal insufflation (page 668) of oxygen can be very satisfactory if the pressure of the gas is not allowed to become too high. The natural tendency in an emergency in which artificial breathing is necessary is to overdo the latter; with manual methods little harm can be done to the patient but with a blast of air or oxygen released into the trachea a great deal of harm can be done. With a mechanical device such as the Drinker respirator it is easily possible to overventilate the lungs, and it may even be possible to distend the alveoli sufficiently to interfere with the pulmonary circulation, particularly if air does not freely enter and leave the respiratory passages. It is probably always better to underventilate slightly than to overventilate when artificial respiration is applied by any method. We have already seen (page 674) that none of these methods can safely be used to expand the lungs of a newborn infant; perhaps the situation would be different if the bronchial muscle were first relaxed, but the reader should clearly understand that this remains to be proved.

CHAPTER XLVII

THE SUPPLY OF OXYGEN TO THE TISSUES

We are now ready to consider the uptake of oxygen by the tissues and the removal of CO_2 from them. As has been mentioned repeatedly in the preceding pages, this is the respiratory process which occurs in all forms of life except anaerobic organisms. The gas exchange in the lungs and the physicochemical equilibria concerned in the transport of the respiratory gases are undoubtedly important, but they are only the means whereby the respiration of the tissues is made possible. Cell respiration is the climax of the entire respiratory process. Since it lies at the basis of the energy changes of the body, cell respiration will be considered in the section devoted to the subject of metabolism (see the next chapter).

In our considerations of the regulation of respiration and of the maintenance of the reaction of the blood we have seen that CO_2 occupies a place of special importance, but tissue respiration deals almost exclusively with the supply and utilization of oxygen, and the removal of CO_2 is a factor of comparatively little moment. There are several reasons for this. One is that CO_2 diffuses so much more readily than oxygen that the former gas can escape from the body much more easily than the latter can enter it. Another is that the body has an abundance of mechanisms for compensating for increases in the amount or tension of CO_2, but it has no comparable means for protecting itself against decreases in the amount or tension of oxygen; there are no reservoirs or reserves of oxygen in the tissues. Finally, an increase in the amount of CO_2 in the tissues may narcotize them but it will not damage them, whereas anoxia, as we have already seen (page 666), "not only stops the machine but wrecks the machinery" (Haldane). The call of the tissues for oxygen is the most fundamental fact of the entire respiratory process.

The mechanisms involved in supplying oxygen to the tissues and removing carbon dioxide from them have already been considered for the most part, but repetition will not be amiss.

The arterial blood reaches the capillaries with the reaction $Hb + O_2 \rightleftharpoons HbO_2$ in equilibrium at an oxygen tension of 90 mm. and a CO_2 tension of 40 mm. The blood contains 20 ml. of oxygen per 100 ml. Of this about 0.3 ml. is in physical solution in the plasma. As long as the blood is in the thick-walled arteries and arterioles nothing can happen to disturb the equilibrium, but in the capillaries the plasma is separated from the tissue fluids only by the permeable endothelial wall. The tension of oxygen in the tissue fluids is lower than that in the plasma because oxygen is constantly diffusing from the former into the cells which utilize it. If the tissue is at rest the oxygen requirement is only that necessary to maintain the physiological structure (semipermeability, separation of constituents, etc.). A fair estimate of the oxygen tension in the fluid surrounding a tissue at rest is about 22 mm.,[132] which is a little lower than that of venous blood (40 mm.). When the blood reaches the capillaries the oxygen molecules pre-

viously held in the plasma under a tension of 90 mm. are forced through the capillary wall because the tension outside the wall is only 22 mm.; they reach the tissue fluid and move on to the tissue cells. The tension of oxygen in the plasma rapidly falls, and this immediately leads to a dissociation of oxygen from combination with hemoglobin. The oxygen molecules liberated from hemoglobin diffuse out of the erythrocytes into the plasma, and thence through the capillary wall. At the same time CO_2 diffuses into the blood because its tension in the tissue fluid is 45 mm. or more and in the arterial blood only 40 mm.; the hemoglobin becomes more acid and its ability to hold oxygen is therefore decreased, so that more oxygen molecules are made free to diffuse out into the plasma. By the time the blood traverses the capillaries and enters the veins it contains about 15 ml. of oxygen per 100 ml. and has an oxygen tension of about 40 mm. (i.e., the oxygen tension of venous blood is not quite as low as that of the tissue fluid, so that a continuous "suction" for oxygen exists). Although the arterial blood contains 20 ml. of oxygen per 100, only 5 ml. of it is given up to resting tissues, i.e., only 25 per cent of the available oxygen is utilized. This is sometimes called the *coefficient of utilization.*

If the tissue is active and not resting the "suction" for oxygen is greater because the tension of oxygen in the tissue fluids is reduced, possibly even to zero if the cells are using oxygen very actively. At the same time the CO_2 tension and hydrion concentration of the tissue fluids are increased. Consequently much more oxygen is taken from the blood, which may emerge on the venous side containing less than 10 ml. per 100 during moderate activity and as little as 5 ml. per 100 during very vigorous exercise. Since active tissues also produce heat the temperature of the blood is raised in passing through the capillaries of such areas and this also helps to remove oxygen from hemoglobin. The blood may give up as much as 80 per cent of its oxygen in passing through an active tissue.*

There is another very important factor in the supply of oxygen to the tissues, namely, the rate of blood flow through the capillaries and the number of capillaries through which it flows. The circulation is so adjusted in resting tissues that the cells get all the oxygen they need, but, as a rule, there is a large margin for further increase both in the rate (or volume) of total blood flow through the tissue and in the total capillary surface over which it is exposed for the diffusion of gases. When a muscle, for example, becomes active, its blood vessels dilate and capillaries previously closed become open. In this way the total amount of oxygen yielded to the tissue can be greatly increased and if—as happens in exercise—the cardiac output and arterial blood pressure also increase, the additional supply of oxygen furnished by circulatory changes may be enormous. Even without any increase in the circulation as a whole the volume of blood flowing through a given tissue is usually increased when the tissue becomes more active. In some cases, such as the salivary gland, the increase in blood flow is out of proportion to the increase in oxygen consumption, and the venous blood leaving the gland during stimulation of the chorda tympani nerve is likely to contain more oxygen than it did before stimulation. The same

*The dissociation of oxygen from oxyhemoglobin ($HbO_2 \rightarrow Hb + O_2$) is greatly influenced by temperature while the combination of oxygen with reduced hemoglobin ($Hb + O_2 \rightarrow HbO_2$) is much less affected. This is a matter of considerable importance because it helps to supply the tissues with the oxygen they need without placing the oxygenation of the blood in the lungs at the mercy of changes in the temperature of the environment. See Barcroft.[15]

thing is true of the kidney and probably of the brain; i.e., when the activity of tissues such as these is increased the local circulation is so greatly augmented that the increased call for oxygen is fully met without the necessity of abstracting even as much oxygen from each unit of blood as was the case when the tissue was at rest. In the muscles the blood is usually reduced more completely during work than during rest; this is probably because the area of the capillaries through which blood passes is increased more markedly in the muscles than in other tissues, the circulatory readjustment in the muscles thus being

TABLE XXVI

ORGAN	CONDITION OF REST	OXYGEN USED PER MINUTE PER GRAM OF ORGAN (ML.)	CONDITION OF ACTIVITY	OXYGEN USED PER MINUTE PER GRAM OF ORGAN (ML.)
Voluntary muscle	Nerves cut. Tone absent	0.003	Tone existing in rest Gentle contraction Active contraction	0.006 0.020 0.080
Unstriped muscle	Resting	0.004	Contracting	0.007
Heart	Very slow and feeble contractions	0.007	Normal contractions Very active	0.05 0.08
Submaxillary gland	Nerves cut	0.03	Chorda stimulations	0.10
Pancreas	Not secreting	0.03	Secretion after injection of secretin	0.10
Kidney	Scanty secretion	0.009	After injection of diuretic	0.113
Intestines	Not absorbing	0.02	Absorbing peptone	0.03
Liver	In fasting animal	0.01-0.02	In fed animals	0.03-0.05
Brain	Inactive (artificial respiration)	0.035	Dyspnea	0.10
Suprarenal gland	Normal	0.045	----------	----------

such as to favor more complete removal of oxygen from the blood while in most other tissues it is such as to increase the total volume of blood passing through a capillary area that changes relatively little.

It is evident that if one wishes to know the amount of oxygen used by a given tissue it is necessary to know (1) the volume of blood which flows through it, as well as (2) the oxygen content of the arterial blood, and (3) the oxygen content of the venous blood leaving the tissue; in order to compare the oxidative processes of different tissues one must also know (4) the weight of the tissue, and the results are usually reported as milliliters of oxygen consumed per gram of tissue per minute. The difficulties in such investigations are biological rather than chemical; the oxygen content of the blood samples can be determined with great accuracy, but the accurate measurement of blood flow is usually difficult and this factor looms much larger in the calculation than the amount of oxygen taken out of each unit of blood. The samples of arterial and venous blood must be collected simultaneously and the blood flow must also be measured at the same time, for otherwise the conditions under which the two samples were

collected may not correspond, and the blood flow when measured may not be that which existed when the samples were collected. These precautions are not always taken by investigators in this field, and the quantitative significance of some of the results obtained is therefore somewhat doubtful. There can be no doubt that increased activity of an organ means increased demand for oxygen. The only doubts concern quantitative data; i.e., how does the amount of oxygen used by one organ compare with the amount used by another, at rest and during activity? Table XXVI gives representative figures.

PART V

METABOLISM AND NUTRITION

By Chalmers L. Gemmill

CHAPTER XLVIII

TISSUE METABOLISM

Physiology is the science of the normal functions and phenomena of living things (Fulton[78]). Behind each function and phenomenon are chemical changes which convert potential energy into useful work. Both physiologists and biochemists have contributed to the study of these chemical changes. Physiologists are interested in the neural and hormonal control of chemical processes and in the chemical reactions involved in organ functions. By reducing the reactions to their simplest terms, biochemists obtain information concerning the possible enzymatic reactions, their substrates, the end products, and the methods of control of such reactions. Physiologists use the knowledge derived from such procedures to explain organ function and the control of such function. Both approaches are necessary for a full understanding of metabolism and the student of the subject must be able to appreciate both viewpoints. For this reason, a chapter on tissue respiration discussed from the standpoint of enzymatic reactions is included in the section on metabolism.

A study of tissue metabolism involves a consideration of the biochemical reactions which release energy for cellular processes. These reactions may be divided into two types, the *aerobic* and the *anerobic*. The magnitude of these two processes in various organs is given in Table XXVII. The aerobic reactions

Table XXVII

Metabolism of Various Tissues Measured Manometrically (Krebs,[27] and Dixon[209])

Animal	Tissue	Temp.	Solution	Q_{O_2}	$Q^{N_2}_G$	$Q^{O_2}_G$
Rat	Kidney	37.5	Ringer	−21.0	+3.7	0
Mouse	Kidney	37.5	Ringer	−20.4	–	0
Dog	Kidney	37.5	Ringer	−18.4	–	0
Rat	Liver	37.5	Ringer	−8.8 to −13.2	+3.3	+0.6
Rat	Brain	37.5	Ringer	−10.7	+19.1	+2.5
Guinea pig	Red cells	37.5	Blood	−0.61	+0.43	–
Rat	Salivary gland	37.5	Ringer	−9 to −24	+3.3 to +6.9	–
Rat	Diaphragm	38.0	Ringer	−6.0	–	–
Rat	Carcinoma	37.5	Ringer	−2.5 to −12.8	+25 to +40	+18 to +30

$$Q_{O_2} = \frac{\text{mm}^3\ O_2}{\text{per mg. (dry weight) per hour}}$$

$$Q^{N_2}_G = \frac{\text{mm}^3\ CO_2}{\text{per mg. (dry weight) per hour}}$$ in an atmosphere of N = anerobic glycolysis.

$$Q^{O_2}_G = \frac{\text{mm}^3\ CO_2}{\text{per mg. (dry weight) per hour}}$$ in an atmosphere of O = aerobic glycolysis.

Aerobic and anerobic glycolysis are expressed in terms of the amount of carbon dioxide liberated from the bicarbonate solution by the lactate formed in these processes.

are those in which molecular oxygen is used to complete the reaction; and the anerobic are those through which energy is liberated without the interaction of molecular oxygen. For example, the formation of lactate from glycogen is considered an anerobic process because it is completed without the interaction of molecular oxygen, but the oxidation of lactate to carbon dioxide and water is regarded as an aerobic process because it requires molecular oxygen for the completion of this reaction. The aerobic types of reactions will be considered first. A discussion of the anerobic types is reserved for the chapter on muscle, since in this tissue, glycolysis, an anerobic process, plays an important role in the liberation of energy.

Respiratory Enzymes

Definition of Oxidation.—Aerobic respiration deals with the oxidation of metabolites in which molecular oxygen is used to complete the reaction and in which carbon dioxide and water are liberated. The term *oxidation* implied originally a taking up of molecular oxygen by a molecule; and the converse process, *reduction,* involved a removal of oxygen from a molecule. Later, it was recognized that the removal of hydrogen from a molecule is also oxidation and that the addition of hydrogen is a reduction. Finally, it was demonstrated that a transfer of electrons without an equivalent transfer of hydrogen or oxygen is also an oxidation. These three processes may be illustrated by the following oxidations and reductions of the ferrous-ferric ion system (Clark[5]).

$$2\ Fe^{++} + \tfrac{1}{2}\ O_2 = 2\ Fe^{+++} + O^{--} \quad (1)$$

$$2\ Fe^{++} + 2\ H^{+} = 2\ Fe^{+++} + H_2 \quad (2)$$

$$Fe^{++} = Fe^{+++} + e \quad (3)$$

Fundamentally, the first and second equations are equivalent to the third, for, in the first reaction, oxygen gains electrons from iron, producing iron with a more positive valence and oxygen with a more negative one; in the second reaction, the ferrous ion loses an electron to the hydrogen ion, thereby becoming a ferric ion and the hydrogen gains an electron, becoming molecular hydrogen. Therefore, oxidation may be defined as a change of an atom or ion from a state of lower to higher valence whereas reduction is a change to a lower valence. Since the substance reduced becomes more negatively charged than the original, it acts as a base for attracting hydrogen ions. The taking up of hydrogen, therefore, may be a secondary reaction to the electron shift. Hydrogen may be transferred primarily, or an electron may be transferred followed by secondary hydrogen transfer. However, which of these two processes occurs depends on the dissociation constant of the reduced substance and on the hydrogen ion concentration of the medium. The terms *hydrogen acceptor, electron acceptor, hydrogen donator,* and *electron donator* may be applied to the respective atoms or ions involved. It is obvious from the examples given, that every oxidation involves a simultaneous reduction.

Cyclic Processes.—Many organic substances have the ability to combine with molecular oxygen. Some of these oxidations may proceed with explosive violence. This fact has given rise to the idea that these reactions represent a direct interaction of oxygen with the organic material. Closer study has revealed that these reactions are, for the most part, indirect and cyclic processes. In the biological field, indirect and *cyclic* processes are also employed for oxidation. The majority of the organic molecules used for food materials are oxidized very

slowly outside the body. In contrast, when inside the body these molecules or parts of the molecules are destroyed very rapidly through accelerating mechanisms which involve enzymes, coenzymes, and carriers—reactions which are cyclic and indirect processes. These findings, although for the most part made on isolated enzymatic systems, are being applied to normal tissue metabolism, vitamin deficiencies, and hormone activity, and will, in the future, be used to explain many other normal and pathological metabolic changes. Therefore, a thorough understanding of the fundamental principles of biological oxidations is essential for the appreciation of the modern trends in metabolic study and of the future advances in this field.

Enzymatic Activation.—Two general ideas have dominated the development of biological oxidations. The one, sponsored chiefly by Warburg, is that molecular oxygen must be activated by an enzymatic process before the organic molecule may be oxidized. The other, developed from the work of Wieland and Thunberg, is that the hydrogen atoms in the organic molecule must be activated by a catalyst before being removed by molecular oxygen or any other suitable hydrogen acceptor. The enzymes involved in the activation of oxygen are called *oxidases* and those for the activation of hydrogen are termed *dehydrogenases.* It was discovered that the majority of enzyme systems involving hydrogen transfer do not enable the activated hydrogen to be transferred to molecular oxygen unless the oxygen is also activated by its specific catalyst. This finding led to a coordination of the two schools of thought and resulted in the theory that the hydrogen and oxygen are activated and are united through a chain of specific carriers.

The terms *dehydrogenase, oxidase, activation,* and *carrier* need further explanation. By definition, an *enzyme* is a biological catalyst that accelerates a reaction to its equilibrium point. A *dehydrogenase,* in the true sense of the word, accelerates a transfer of hydrogen from the metabolite to an acceptor as in reaction 4.

$$AH_2 + B \rightleftharpoons A + BH_2 \qquad (4)$$

However, it may also accelerate the reversal of this reaction if substances A and BH_2 are added to the enzymatic solution. Here, the hydrogen is transferred from the so-called acceptor and given to the so-called donator. Since, in this case, a dehydrogenase brings about an increase in the velocity of a reaction until the equilibrium point is reached, the original meaning of the term, *dehydrogenase* (i.e., an enzyme which removes hydrogen), has lost its significance. This term is still used, however, to describe an enzyme which accelerates the transfer of hydrogen, generally from the metabolite to the acceptor. As explained in the first section, this transfer may be one of hydrogen or one in which an electron is transferred with or without a secondary transfer of hydrogen. The end result is the same, the metabolite is oxidized and the hydrogen or electron acceptor is reduced. There are many dehydrogenases; in fact, it has been claimed that each organic substance metabolized by the tissues has its specific dehydrogenase.

Many theories have been presented to explain the actual mechanism of enzymatic activation of hydrogen in an organic molecule and of molecular oxygen. None of these theories is satisfactory. Therefore, *activation* may best be defined in terms of the result: it enables an organic molecule, otherwise stable, to give up hydrogen at a finite velocity when acted on by a dehydrogenase, and it enables molecular oxygen to react more rapidly with hydrogen in the presence of an oxidase.

Cytochrome Oxidase.—Oxygen has a specific enzyme for its activation. Knowledge of this enzyme has come from three entirely separate sources: the study of the formation of indophenol by the indophenol oxidase, the study of the respiratory ferment by Warburg, and of cytochrome oxidase by Keilin. It is now known that the enzyme is the same in the three systems.

Indophenol oxidase, an enzyme which accelerates the conversion of α-naphthol and dimethyl-p-phenylenediamine (Nadi reagent) to indophenol, has been known for a long time. This enzyme is present in a majority of animal tissues, in bacteria, and in yeast. Because only nonbiological reagents were used in the test for the presence of this enzyme, little importance was attached to the results except that the presence of a powerful oxidase in tissues was noted. The similarity of this enzymatic activity to that of cytochrome oxidase will be discussed later.

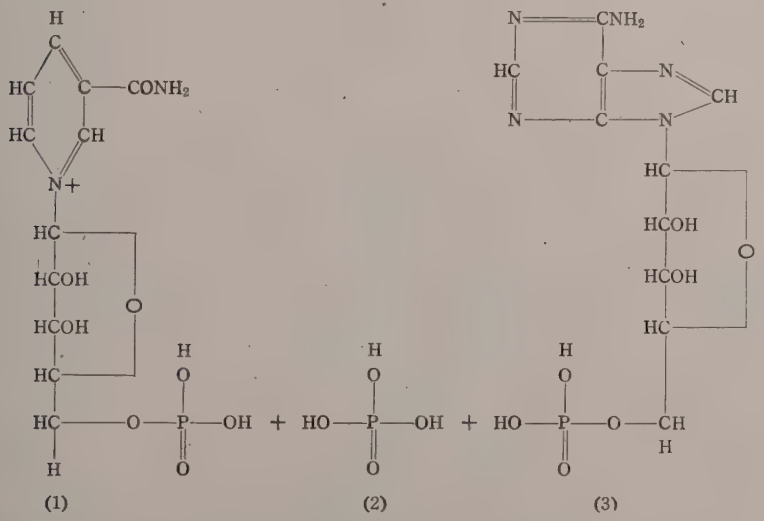
The second independent line of attack came from the work of Warburg. Warburg postulated that the oxygen-transferring enzyme of respiration contained iron because of the ability of cyanide and carbon monoxide to inhibit respiration. It is well known that heavy metal ions react with cyanide to form compounds which do not dissociate easily. In the case of a heavy metal catalyst this combination would block the active group and prevent the reduction of the heavy metal. Not all heavy metal catalysts are, however, inhibited by cyanide, for the inhibition depends on the nature of the metal and on the type of linkage to other parts of the molecule. But, since cell respiration is nearly 100 per cent inhibited by suitable cyanide concentrations, Warburg stated that the respiratory enzyme was an iron-containing component of a heme type. The evidence that it was of a heme type came from an indirect determination of the absorption spectrum of this compound. Having discovered that carbon monoxide inhibits the oxygen uptake of yeast, and knowing that the reaction of carbon monoxide with hemoglobin is reversed by the action of light, Warburg[38] radiated yeast with light of various wave lengths and measured the respiratory activity at these wave lengths. He discovered that light dissociated the combination of carbon monoxide and the respiratory ferment. This dissociation increased respiration. In this reaction it was evident also that different wave lengths had different efficiencies. From this study of the relative effects of various wave lengths, Warburg calculated the absorption spectrum of the respiratory ferment and found that it closely resembled that of known carbon monoxide derivatives of hematin.

The connection of indophenol oxidase and the respiratory ferment with the cytochrome system resulted from the work of Keilin. Keilin[23-26] studied the indophenol oxidase system in yeast and found that the properties of this enzyme were very similar to those found by Warburg for his respiratory ferment. The indophenol oxidase activity was inhibited by cyanide or carbon monoxide and the inhibition caused by carbon monoxide was reversed by light. In fact, all the various reagents used to study the respiratory ferment reacted in the same manner with the indophenol oxidase. Since molecular oxygen cannot combine directly with cytochrome, and since both the respiratory ferment and indophenol oxidase may reduce oxidized cytochrome, Keilin postulated that these enzymes were the same. The specific property of this enzyme is to activate oxygen in order that it may be used in the reduction of cytochrome—a true cytochrome oxidase function. Later work (Stotz, Sidwell and Hogness[34]) has shown that the indophenol oxidase metabolizes its nonbiological substrate through cooperation with cytochrome.

Respiratory Coenzymes

Several important coenzymes of the respiratory mechanisms have been isolated and their constitution determined. A coenzyme may be defined as a substance produced by living cells, necessary for enzymatic reactions, of lower molecular weight than the protein portion of the enzyme, heat stable and dialyzable (Baumann and Stare[3]). The distinction between coenzyme and enzyme varies in different cases. In some, the active group, which is called the coenzyme, is combined with a protein that is inactive by itself; in other cases, the coenzyme is combined with a protein which has true enzymatic activity by itself. In this latter case, the coenzyme further accelerates the natural activity of the proteins. The respiratory coenzymes are compounds which may be reversibly oxidized and reduced. By this property they act as hydrogen or electron acceptors or donators.

Pyridine Nucleotides.—It has been known for a long time (Harden and Young[21]) that the fermentation of cell-free extracts of yeast was accelerated by the addition of a thermostable fraction of yeast juice. This portion was termed "coenzyme" as it accompanied the enzyme from yeast. The general distribution and importance of this coenzyme were demonstrated by Meyerhof,[31] who showed that the same activity could be obtained from a substance present in muscle and in milk. This substance not only aided fermentation but also accelerated the oxygen uptake of muscle. Through the work of Warburg and his associates,[40, 41] the chemical nature and the specific biological importance of this substance has been disclosed. It is a diphosphopyridine nucleotide consisting of adenine, nicotinic acid amide, two molecules of phosphoric acid and two of pentose:



(1) + (3) = Diphosphopyridine nucleotide + H_2O

(1) + (2) + (3) = Triphosphopyridine nucleotide + $2H_2O$

Various names have been given to this substance: coenzyme I, yeast coenzyme, codehydrase I, and others. Since the constitution has been determined, it would be best to call it by its chemical name, diphosphopyridine nucleotide or DPN. Warburg isolated another coenzyme in his studies of the oxidation of hexosemonophosphate by red blood cells. This coenzyme is similar to DPN with the exception that it contains three molecules of phosphoric acid. This molecule has been called coenzyme II, but since the chemical constitution is known, it will be called triphosphopyridine nucleotide or TPN.

The remarkable discovery which came out of this work was the high degree of specificity of DPN and TPN in their coenzymatic activity, since most of the enzymes require either DPN or TPN and only a few may use both interchangeably. Why one molecule of phosphoric acid in the coenzyme should make such a difference has not been explained. The substrates which are known to be oxidized by means of the pyridine nucleotides are given in Table XXVIII.

TABLE XXVIII

SUBSTRATES OXIDIZED BY MEANS OF PYRIDINE NUCLEOTIDES (BALL[1])

SUBSTRATE	ENZYME SOURCE	COENZYME	
		DPN	TPN
Hexosemonophosphate	Red blood cells	–	+
	Yeast	–	+
Triosephosphate	Muscle	+	–
	Yeast	+	–
Alcohol	Yeast	+	–
Lactate	Muscle	+	–
Glycerolphosphate	Muscle	+	–
Glutamic acid	Liver	+	+
	Yeast	–	+
	B. coli	–	+
	Plants	+	–
Glucose	Liver	+	+
β-hydroxybutyrate	Muscle	+	–
Malate	Muscle	+	–

It may be noticed from the table that the enzyme for the oxidation of glutamic acid uses both DPN and TPN but only when the enzyme source is from the liver. Glucose dehydrogenase also uses both coenzymes.

Riboflavin Phosphoric Acid.—In his study of hexosemonophosphate oxidation, Warburg[39] discovered a coenzyme which aided in the oxygen uptake of that system. This coenzyme was shown to be a phosphorylated riboflavin which needed for its activity a protein molecule. The complete molecule is called a flavoprotein or yellow enzyme. More recent work has shown that this coenzyme is a flavin adenine nucleotide with the following components.

Phosphate—ribose—adenine
|
Phosphate—ribose—flavin

The similarity of this molecule to DPN may be seen by writing formula (1) of DPN in the same manner.

Phosphate—ribose—adenine
|
Phosphate—ribose—nicotinic amide

In addition to this flavoprotein, numerous others have been described. The chemical and biological properties of the more important of these compounds have been summarized in Table XXIX.

TABLE XXIX

PROPERTIES OF FLAVOPROTEINS (DIXON[7])

	YELLOW ENZYME OF WARBURG	LACTOFLAVIN	COENZYME FACTOR	COENZYME OF D-AMINO ACID OXIDASE
Source	Yeast	Milk	Heart	Kidney
Color	Yellow	Orange-red	Yellow	
Absorption bands at	380:465	350:450	359:451	
Molecular weight	78,000	280,000		
Reacts with methylene blue	+	+	+	+
Oxygen	+	+(?)	−	+
Cytochrome C	+	+	−	
Red. DPN	+	+	+	−
Red. TPN	+	+(?)	−+*	−

*Two forms present (von Euler[37]; Green[16]).

Flavoprotein was shown by Warburg to be the essential link between the TPN and oxygen in the oxidation of hexosemonophosphate.

Hexosemonophosphate + enzyme + TPN + flavoprotein + O_2.*

Since this system is not inhibited by cyanide, it was thought that such a mechanism might explain the residual oxygen uptake in some cells following poisoning with cyanide. Recent work, however, has given a more important position to the flavoproteins. Green and his associates[16] and von Euler[37] have described a "coenzyme factor" or "diaphorase" which had the property of oxidizing the reduced DPN and of being reoxidized by molecular oxygen or cytochrome. Straub[35] isolated from heart muscle a new flavoprotein which Green and Corran and Straub[20] had shown to be identical with this coenzyme factor. Diaphorases I and II which act with DPN and TPN, respectively, have been described (Alder, von Euler and Günther[12]). Since the DPN or TPN do not have the ability to reduce cytochrome or to take up molecular oxygen, this coenzymal link is necessary between the DPN or the TPN systems and cytochrome. These findings place flavoproteins in the direct line of oxidations and these substances may be considered as dehydrogenases of DPN or TPN.

Cytochrome.—Although not considered as a coenzyme, cytochrome is a natural carrier and will be discussed in this section. MacMunn[29, 30] described a pigment in muscle which, when reduced, had characteristic absorption bands and which, when oxidized, had none. He extracted this pigment from muscle and gave to the substance the name "modified myohematin." This pigment was forgotten until Keilin discovered the wide distribution of this substance in tissues that use oxygen and described its important role in oxidative processes. Keilin gave to this substance the name *cytochrome*. Cytochrome has been subdivided into three components, *a*, *b*, and *c*, by their characteristic absorption spectra.

Cytochrome *c* is soluble and may be readily extracted from cells. It has been purified and partially identified (Theorell[36]). The biological importance of

*In this and the following section the components of the enzyme systems will be listed with + signs. This does not denote a stoicheiometric reaction between components; it merely shows the components that must be present in order to obtain a reaction.

the cytochromes is that they may be rapidly oxidized and reduced, and when they are present with special enzyme systems, they aid in the acceleration of oxygen uptake. It has been calculated that practically all of the respiratory activity of yeast is connected with the cytochrome system. Other examples of cytochrome activity will be given in the following sections.

CLASSIFICATION OF RESPIRATORY ENZYME ACTIVITIES

Respiratory enzymatic activity may be classified by the number of components necessary for oxidation of the substrate.

Aerobic Dehydrogenase Activity.—The aerobic dehydrogenase chain possesses the smallest number of components. The enzymes activate hydrogen of the substrate, but the chain requires neither cytochrome nor cytochrome oxidase, and can reduce dyes or oxygen directly. The outstanding enzymes of this group are xanthine oxidase, which has the property of oxidizing xanthine or aldehydes, and d-amino acid oxidase, which acts on the d- form of amino acids—the "unnatural" amino acids. Warburg and Christian[42] have shown that d-amino acid oxidase is a flavoprotein, and Ball[14] has demonstrated a comparable substance associated with xanthine oxidase. These two enzymes, therefore, carry out their reactions through the following components:

$$\text{Substrate} + \text{flavoprotein} + O_2$$

Uricase also belongs in this group but it is unique, for it uses oxygen as a specific receptor and does not need a flavine adenine nucleotide for its activity:

$$\text{Uric acid} + \text{uricase} + O_2$$

This particular reaction has been studied extensively by Keilin and Hartree.[24]

Anaerobic Dehydrogenase Activity.— The anaerobic dehydrogenase chain forms the next group. It is termed anaerobic because it needs intermediate substances to complete the oxidation of substrates. The enzymes activate hydrogen so that it either reduces cytochrome directly or reduces DPN or TPN which in turn reduces a flavoprotein and then finally cytochrome. It was originally thought that a few dehydrogenase systems in this class had the property of producing reduction of cytochrome directly by means of activated hydrogen. These enzymes in this system were believed to be lactate dehydrogenase from yeast, the α-glycerophosphate dehydrogenase in muscle, and the succinate dehydrogenase. Recent experimentation indicates, however, that some of these dehydrogenase systems may require another intermediate substance between the substrate and cytochrome. Hopkins[22] and Stern,[33] in work with the succinate dehydrogenase have described an additional activating factor necessary for the complete reaction, and it is possible that another such additional factor may be needed for lactate dehydrogenase activity.[17] Further investigation of this question is necessary, however, before these factors can be definitely added to the scheme. At the present time the following components are considered to enter into this type of reaction:

$$\text{Substrate} + \text{dehydrogenase} + \text{cytochrome} + \text{cytochrome oxidase} + O_2$$

All of the other types of anaerobic dehydrogenases require the complete system:

$$\text{Substrate} + \text{dehydrogenase} + \text{DPN (or TPN)} + \text{flavoprotein} + \text{cytochrome} + \text{cytochrome oxidase} + O_2$$

Each carrier may react with its immediate neighbor. The flavoprotein used by Warburg in his red blood cell system combined directly with oxygen. However, Theorell observed that the velocity of the uptake of oxygen was greater if the cytochrome system was also present. Therefore, the more normal system uses the complete chain. All of the substrates listed in Table XXVIII are oxidized by the complete system.

Many other carriers may be placed in these systems. For example, Szent-Györgyi[10] claims that the succinate-fumarate system and the malate-oxaloacetate systems act as hydrogen transporters with a flavoprotein joining the two systems. The ability of one system to oxidize or reduce another depends on the oxidation-reduction potential of the two systems and the carrier. (Green et al.[15, 18, 19].) Whether all of these systems play a rôle in the oxidation of substrates in the intact cell is not known; however, the component parts are present and may be isolated experimentally.

The final result of the oxidations described above is the production of CO_2 and of water. The hydrogen in the water may be the original hydrogen of the substrate if hydrogen transport takes place along the whole chain; or, if electron transport takes place, the electrons will act on the oxygen in such a manner that it will combine with any hydrogen ion present in the solution. If hydrogen peroxide is formed, it will be acted upon by either a *peroxidase* or a *catalase,* either of which will convert the peroxide into water and oxygen. The peroxidase has the property of activating the oxygen as it is formed in order that it may again be used in biological oxidations.

Decarboxylation.—The carbon dioxide formed in biological oxidations comes from a process of decarboxylation. This process also needs a coenzyme. Neuberg[32] demonstrated that an enzyme, carboxylase from yeast, had the property of converting pyruvic acid into acetaldehyde by a process of decarboxylation. Auhagen[13] showed that this enzyme needed a coenzyme (cocarboxylase) which Lohmann and Schuster[28] later isolated. The latter observers showed that the coenzyme is phosphorylated vitamin B_1.

Most of the carbon dioxide formed in biological oxidations is supposed to come from decarboxylation. This means that food material must pass through an organic acid stage before being finally burnt. It also means that the carbon dioxide given off by the body comes from the carbon and oxygen in the food material. The other end product, water, contains the molecular oxygen that we breathe and the hydrogen that was originally present in organic food material. This hydrogen may have come not from a given molecule which became oxidized but from the store of hydrogen ions in the body. The difficulty of following oxygen, carbon, or hydrogen through the maze of metabolic events is obvious. Tagged atoms will be of great aid in the final elucidation of these processes.

CHAPTER XLIX

ENERGY METABOLISM

Metabolism, a term derived from a Greek word meaning change, may be defined as "the sum of all the physical and chemical processes by which living organized substance is produced and maintained, and also the transformation by which energy is made available for the uses of the organism". (Dorland[11]). The formation of molecules of higher from those of lower energy content and their incorporation into organized tissue constitute the process of *anabolism.* This has not been studied as extensively as has the process of *catabolism,* the breakdown of large unstable molecules with the release of energy. The reason that catabolism has received the greater attention is that one of the essential features of the breakdown is an oxidative process, the magnitude of which may be measured easily by determining the total energy evolved or the quantity of oxygen used. On the other hand, it is very difficult to follow the chemical and energy changes associated with anabolism.

METHODS

Two general methods are available for the study of metabolism in animals. In the first, the constituents of the ingested food are compared with those of the excretory products. From this a balance may be constructed showing the amounts of material left in the body and the types of end products produced. This method of experimentation deals with what has been termed *general metabolism.* In constructing a balance sheet of general metabolism, substances must be selected which are common to intake and output. For the most part the intake comprises water, oxygen, proteins, fats, carbohydrates, and minerals. The output consists chiefly of carbon dioxide, water, minerals, and various nitrogenous constituents of the urine. The dissimilarity in chemical structure between the substances taken in and most of those excreted limits us, in balancing the one against the other, to a comparison of the elements into which each can be broken by chemical agencies. From balance sheets of intake and output of carbon and nitrogen and from information obtained by determining the ratio between the amounts of carbon dioxide excreted and oxygen consumed (the respiratory quotient), it is possible to draw some conclusions regarding the relative amounts of protein, fat, and carbohydrate that have been involved in the metabolic processes.

The second method used in the study of metabolism deals with the chemical changes which individual foodstuffs undergo between ingestion and excretion. In this, instead of contenting ourselves with a comparison of the raw material taken in and the finished product of the animal factory, we seek to learn something of the particular changes undergone by each kind of material as it yields energy for cellular processes or enters into the repair of worn-out tissues. Such is the method of studying the subject of *special metabolism.* In this case balance sheets tell practically nothing of the changes under investigation. For example, suppose that when a substance, A, is fed, an amount of

another substance, B, is found in the urine. This fact may be interpreted in any one of several ways; it may mean that B is one of the intermediate products of the breakdown of A; if only a small amount of B appears, it may signify that there are two or more ways of metabolizing A, B representing the end product of only one of these chemical pathways; finally, it may be interpreted to mean that B is derived from an intermediate product by a side reaction and is not formed in the direct line of changes. Obviously experiments directed toward a study of general metabolism may give little or no information concerning special metabolism.

Special Methods

Various special methods have been employed in investigating problems in special metabolism. The more important of these are described below.

Feeding Experiments.—In the prosecution of experimental work directed toward the determination of the intermediate products of the metabolism of some substance a method of exclusion may be used. The chemically possible intermediates are fed to an animal and the excreta studied to determine which of these are oxidized in the body and which pass through unchanged. For example, let us suppose that oxalic and acetic acids are the chemically possible intermediates in the breakdown of some ingested substance. They are fed and it is found that oxalic acid appears in the excreta while acetic acid does not; the latter has apparently been oxidized. Therefore, acetic acid may be an intermediate product. This method, however, gives only circumstantial evidence.

Another method used extensively in this type of work involves the introduction of a ring in the molecule of the substance under investigation. It is then fed with the expectation that the ring may block part of the oxidative processes to which the substance is normally exposed and thus allow intermediate compounds to appear in the urine. One serious objection to this method is that introduction of the ring may so change the molecule that its metabolism does not proceed along the usual pathway.

Perfusion.—Perfusion of organs has been used in studying special metabolism. Valuable information has been obtained by adding substances to the perfusing fluid and detecting the intermediate products in the perfusate. Older techniques proved inadequate because the perfused organ soon became edematous, but modern methods permit perfusion for fairly long periods of time and enable the experimenter to follow the intermediate metabolism with fair accuracy. Sometimes analysis of samples of blood from the artery and vein of an organ in situ will give valuable information concerning metabolic changes taking place in that organ.

Tissue Slices.—During the past ten years the tissue slice method has become very popular among investigators in this field of physiology. Thin slices of tissue are shaken in a medium containing the substance to be metabolized. Subsequently the possible intermediates are determined by microchemical analysis of the medium and tissue. This method has the advantage over that of perfusion in that many experiments may be performed and the results treated statistically. It possesses the disadvantage that when the tissue has become abnormal no obvious signs of this make their appearance. Also, the amounts of material formed by the metabolic changes in thin slices of tissue are so small that they are difficult to determine with great accuracy.

Isotopes.—For many years, the physiologist has accepted the physicist's concept of the atom in dealing with solutions, for example, that of the hydrogen ion. More recently the newer ideas of the physicist have come into use in metabolic studies. Especially is this true of the labeled molecules (i.e., molecules made radioactive or those containing natural isotopes); hence it becomes necessary to discuss their production and use.

The new concepts of the physicist are based on the following discoveries (Du Bridge[55]):

1. The discovery, measurement, and separation of isotopes of the chemical elements (Aston, Bainbridge, Urey).

2. The development of machines for accelerating charged particles to very high energies, i.e., the cyclotron (Lawrence) and the electrostatic generator (Van de Graaff).

3. The transmutation of elements.
   a. By natural alpha-particles (Rutherford, 1919).
   b. By artificially accelerated protons (Cockcroft and Walton, 1932).

c. By deuterons (Lawrence, 1933).
d. By neutrons (Feather, 1932).

4. The discovery of the positron (Anderson, 1932).
5. The discovery of the neutron (Chadwick, 1932).
6. The discovery of induced radioactivity (Curie-Joliot, 1934).

Structure of Atoms.—A working knowledge of the structure of the atom is necessary for an understanding of the application of nuclear physics to metabolic study. The *atom* consists of two portions, the nucleus and the surrounding electrons. The nucleus is composed of *neutrons* of mass 1, carrying no charge, and the *protons* of mass 1, carrying a positive charge. The sum of the neutrons and protons determines the mass or atomic weight of the atom. The positive charges on the protons in the nucleus are balanced by electrons, units with mass of 0.00055 and carrying a negative charge. The electrons are arranged in planetary systems around the nucleus. The complete designation of an atom may be given as X_z^w where z is the atomic number (i.e., the number of protons in the nucleus or the number of electrons in the planetary system), X is the symbol of the element and w is the closest whole number to the atomic weight. The symbol for an electron is e_{-1}^{0}, which means that its mass approximates 0 and it carries a charge of –1. The electrons in the planetary orbits are easily removed. In contrast, it requires tremendous energy to remove a neutron from the nucleus of an atom.

An isotope of an atom is an element that has the same number of electrons in the planetary space but has more or fewer neutrons in the nucleus than the original atom. Since the number of electrons determine the chemical characteristics of the atom, this factor would not change. The mass changes because of the addition or subtraction of unit masses, the neutrons, from the nucleus. Isotopes are divided into two types, *stable* and unstable or *radioactive.*

TABLE XXX

ATOMIC NUMBERS, ATOMIC WEIGHTS AND STABLE ISOTOPES OF SOME ELEMENTS OF BIOLOGICAL INTEREST (ROBERTSON[63])

ELEMENT	SYMBOL	ATOMIC NUMBER	ATOMIC WEIGHT	MASS NUMBER OF ISOTOPES
Hydrogen	H^1	1	1.0081	1,2,3
Heavy Hydrogen (Deuterium)	H^2 or D	1	2.0147	2,0
Lithium	Li	3	6.94	6,7
Carbon	C	6	12.00	12,13
Nitrogen	N	7	14.01	14,15
Oxygen	O	8	16.00	16,17,18
Sodium	Na	11	23.00	23
Magnesium	Mg	12	24.32	24,25,26
Phosphorus	P	15	31.02	31,0
Sulfur	S	16	32.06	32,33,34
Chlorine	Cl	17	35.46	35,37
Potassium	K	19	39.10	39,40,41
Calcium	Ca	20	40.08	40,42,43,44
Iron	Fe	26	55.84	54,56,57
Lead	Pb	82	207.22	204,206,207,208

The isotopes are used in metabolic study for labelling certain atoms in order that their metabolic history may be traced through the body. In order to be suitable for a tag, an isotope must not be present in the body in any large concentration, must be easy to determine, and if unstable, must have a life of suitable period for biological research. The stable isotopes used in metabolic research are H_1^2, O_6^{18}, N_7^{15}, and C_6^{13}. (Table XXX.) Many radioactive isotopes have been prepared, P_{15}^{32} being one that has been used extensively for the study of phosphate transfer in the body. The radioactive isotopes may be divided into two classes, those naturally occurring and those artificially prepared. The naturally occurring isotopes, such as radioactive lead, have been used as tracers. Since only a few such atoms are known, the production of artificial radioactive isotopes has enlarged this field.

There are several methods of preparing isotopes. The stable isotopes may be obtained by fractionation of the naturally occurring elements. Heavy hydrogen, H_2^1, consisting of one neutron and one proton in the nucleus and one electron in the planetary system, occurs in water, and heavy nitrogen, N_7^{15}, with 8 neutrons and 7 protons in the nucleus and 7 electrons in the planetary system is present in atmospheric air.

Radioactive isotopes are prepared by the ejection of neutrons from the nucleus. This may be done by the action of protons, deuterons, alpha-particles or gamma-rays. Alpha-particles are liberated during the decomposition of radium and consist of a helium nucleus. Thus they are composed of two neutrons and two protons and carry a positive charge of 2, the symbol being He_2^4. The γ rays liberated in the decomposition of radium are true radiations of strong penetrating power. The classical example of the method for separation of neutrons is that of the action of alpha-particles on beryllium.

$$Be_4^9 + He_2^4 = C_6^{12} + n_0^1$$

Another example is the bombardment of beryllium with deuterons, the ions of heavy hydrogen.

$$Be_4^9 + H_1^2 = B_5^{10} + n_0^1$$

In the first equation beryllium is converted into carbon by the action of alpha particles, and in the second it is converted into boron by the action of deuterons. In both cases neutrons are liberated from the nucleus. It is to be noticed that the sum of the atom numbers as well as that of the atomic masses balances on both sides of the equation. The total charge on each side of the equation must be equal.

The number of transmutations are infinite. If an unstable isotope is formed, it is converted into a stable form by the ejection of a positron or an electron. A *positron* is a particle of similar mass to an electron but carrying a positive charge. A proton in the nucleus is considered to be formed from a neutron and a positron, and a neutron is created by the combination of a proton and an electron. Thus positrons and electrons may be split from protons and neutrons with the resulting production of neutrons and protons. The symbol for the positron is e_1^0, meaning that it has a mass almost of 0 and a charge of 1.

$$\text{Proton } (H_1^1) = \text{neutron } (n_0^1) + \text{positron } (e_1^0)$$

$$\text{Neutron } (n_0^1) = \text{proton } (H_1^1) + \text{electron } (e_{-1}^0)$$

An example of such a conversion is the change of C_6^{12} to N_7^{13}. N_7^{13} is an unstable isotope and is converted into the stable C_6^{13}:

$$C_6^{12} + H_1^1 = N_7^{13}$$

$$N_7^{13} = C_6^{13} + e_1^0$$

In the first reaction, the carbon atom has gained a proton, making six neutrons and seven protons in the nucleus and seven electrons in the planetary space. This gives the atom the characteristics of nitrogen with an atomic weight of 13. One of the protons loses a positron, becoming a neutron. The atom now has seven neutrons and six protons in the nucleus, and six electrons in the planetary space. This gives the atom the characteristics of carbon with an atomic weight of 13.

Radioactive phosphorus is prepared by the action of a neutron on sulfur:

$$S_{16}^{32} + n_0^1 = P_{15}^{32} + H_1^1$$

In this reaction the neutron replaces a proton in the sulfur atom. The resulting atom has 17 neutrons, 15 protons and 15 electrons, giving it the characteristics of phosphorus with an atomic weight of 32. It has a half life of 14.8 days, ample time for most metabolic studies. Other examples will be given under their appropriate subjects.

The radioactivity of the unstable isotopes does not affect biological function, as the radioactive atom emits radiation only at the end of its career, when it changes into another element. Thus, very few of the tracer elements emit radiations during the course of a biological experiment. The small change in atomic weight of the isotopes does not affect the ability of the ion to diffuse through membranes or to take part in metabolic interchange. A serious objection is that the isotope may not be firmly bound to the compound under study and thus be lost or chemically transferred during the time of study. It has been shown, however, that heavy hydrogen bound to carbon as in a methyl group cannot be removed by exchange with water or even by treatment with hot acid or alkali. Therefore, if deuterium is removed by a reaction in the body, this interchange represents a biological change in the position of the atom. A similar stability has not been demonstrated for all isotopes and any reaction involving these substances must be accepted with the reservation that the isotope is assumed to be firmly bound in the molecule and can only be removed during the course of a true biological reaction.

THE ENERGY BALANCE

One of the forms of metabolic investigation which has yielded very important information is the study of the body's input and output of *energy*. The basis of such work is the application to biological systems of the first law of thermodynamics.

The First Law of Thermodynamics.—Count Rumford, at the end of the eighteenth century, noticed that the mechanical energy expended during the boring of a cannon was roughly proportional to the amount of heat evolved in the process. During the fifth decade of the last century Mayer, Joule and Helmholtz independently stated that a definite amount of mechanical energy produces a definite amount of heat. Their observations and discussions led to the general conclusion that energy is neither gained nor lost when it is converted from one form to another. This "law of the conservation of energy" has been applied to all forms of energy: kinetic, thermal, electric, and chemical. According to it any system in a given condition contains a definite quantity of energy and, when the system undergoes change, any gain or loss of its internal energy is equal to the loss or gain in the energy of surrounding systems (Lewis and Randall[59]). The application of this law to biological systems was one of the outstanding events in the development of our knowledge of metabolism. It involved a comparison of the actual energy expended by an animal with the energy supplied to the animal either from ingested foodstuffs or from the reserve stores of material in the body. This comparison is called the energy balance of metabolism.

The unit of energy used in work with biological systems is the large Calorie, indicated by capital C, which is the amount of heat required to raise the temperature of one kilogram of water through one degree Centigrade of temperature. The value of the Calorie varies with the level at which the temperature change of the water occurs; generally the change taken is that between 15° C. and 16° C. The caloric value of the energy supplied in the food is determined by burning a measured quantity of material in a bomb calorimeter. This apparatus is placed in a known amount of water at a certain temperature. After combustion of the material inside the bomb the resulting rise in the temperature of the water is multiplied by the volume of the water in liters to ob-

tain the caloric value. Another method (Benedict and Fox[71]) consists in measuring the oxygen used in burning the food material and then converting this value into Calories. This is an *indirect method* of determining the energy content of foodstuffs and stands in contrast with the *direct method* of the calorimeter. The caloric values obtained for commonly ingested materials are given in Table XXXI.

TABLE XXXI

GASEOUS EXCHANGE, RESPIRATORY QUOTIENT, HEAT PRODUCTION AND CALORIC VALUE OF CARBON DIOXIDE AND OF OXYGEN OF VARIOUS COMMONLY METABOLIZED COMPOUNDS (CARPENTER[50])

MATERIAL	O_2 REQUIRED TO OXIDIZE 1 GRAM ml.	PRODUCED IN OXIDATION OF 1 GRAM		R. Q.	HEAT PER LITER OF	
		CO_2 ml.	HEAT CAL.		O_2 CAL.	CO_2 CAL.
Starch	829.3	829.3	4.20	1.00	5.06	5.06
Cane sugar	785.5	785.5	3.96	1.00	5.04	5.04
Dextrose	746.2	746.2	3.74	1.00	5.01	5.01
Lactic acid	745.9	745.9	3.62	1.00	4.85	4.85
Animal fat	2013.2	1431.1	9.50	0.71	4.72	6.64
Protein	956.9	773.8	4.40	0.81	4.60	5.69
Acetone	1542.9	1157.2	7.43	0.75	4.82	6.42
Ethyl alcohol	1459.5	972.9	7.08	0.67	4.85	7.28

The values given above, especially those for the more complex substances, are still in process of standardization. The values which have been obtained for such materials as glycogen and starch, difficult to obtain in a state of chemical purity, have not been in precise agreement. Although the differences are small they become significant when used in attempts to balance the energy exchange of tissues.

Essentially the same methods are used to measure the energy liberated by the animal body. Here again it may be determined *directly,* by placing the animal in a calorimeter, or *indirectly,* by measuring the amount of oxygen used or the amount of carbon dioxide given off and then converting these values into Calories. From the respiratory quotient the ratio of the volume of carbon dioxide given off to the volume of oxygen taken in during the same interval of time, a rough indication of the type of food material metabolized is obtained. It will be advantageous to give an outline of the techniques of the two methods.

METHODS

The Direct Method

The direct method has the advantage that it measures in Calories the output of energy. When small animals are studied the simplest form of apparatus is a Dewar flask in which the animal is placed and the resulting temperature change recorded by a sensitive thermometer. Meyerhof[85] used this method to determine the heat produced during the formation of lactic acid in frogs' muscles. Hill[82] constructed a differential calorimeter by making use of two flasks in each of which was placed one junction of a thermocouple. In using such an apparatus the animal or tissue is placed in one flask and the other acts as a control whereby the effects of changes in external temperature upon the recording mechanism are excluded. This type of apparatus has been used to study the metabolism of frogs and other small animals.

Calorimeters have been constructed for the purpose of measuring, by the direct method, the heat production of larger animals and man. Usually, as in the case of the apparatus

shown in Fig. 273, they are designed to measure also the gaseous exchange of the subject (indirect calorimetry). This is a valuable provision, for it permits a comparison of the two methods. For the present, we are concerned only with that part of the design involved in the direct measurement of heat production. For this the arrangement is such that the subject may occupy a thermally insulated chamber in which heat lost from the body by radiation and conduction (about three-fourths of the total lost) is removed by a stream of cold water flowing through tubes attached to the inner walls. The number of Calories thus lost by the subject can easily be calculated from the volume of water passing through and the difference in temperature of the ingoing and outgoing water. The change in temperature of the water in degrees Centigrade multiplied by the volume of water in liters gives the Calories carried away from the apparatus during the period. This plus the heat value of the water vaporized from the body of the subject gives the total heat elimination. Any other loss of heat from the calorimeter is prevented by a double copper wall surrounding the chamber. These copper walls are connected with thermocouples so that an electric current is generated when any

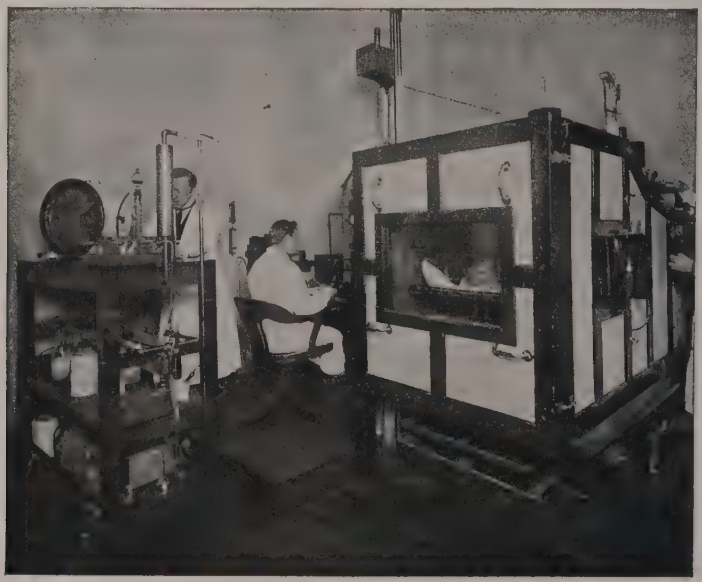


Fig. 273.—Respiration calorimeter of the Russell Sage Institute of Pathology, Bellevue Hospital, New York. At the left is seen the table with the absorption tubes; and in the middle, at the back, the electric control table for regulating the temperature of the double walls of the calorimeter. (Lusk's Science of Nutrition.)

difference in temperature occurs between the walls. If there is a change, temperature equilibrium is restored by passing cold water through coils or by electrical heating. In this manner the two walls are kept at the same temperature and consequently there can be no flow of heat between them. The heat used in vaporizing water from the skin and lungs is measured by collecting the moisture in a sulfuric acid bottle placed in the ventilating circuit and then multiplying its weight in grams by the heat of vaporization of water. At 20° C. the heat of vaporization is 0.586 Calorie per kilogram of water. A factor which must be taken into consideration is the temperature of the subject. Any change in this is noted and multiplied by the specific heat of animal tissue (0.83). If, for example, the temperature of a man weighing 70 kilograms varies one degree, there would be a change of 70 × 0.83 or 58.1 Calories in the heat given off. This calculation is made on the assumption that the temperature change is uniform throughout the body of the subject. The calorimeter used by Du Bois con-

tains a comfortable bed, windows, shelf, telephone, fan, electric light, and stethoscope. The larger calorimeters constructed by Benedict and Atwater contain, in addition, a stationary bicycle for the determination of the heat production during work. The subjects may remain in such chambers as long as twenty-four hours. The expense of installation and maintenance of calorimeters and the time needed for their operation are so great that the direct method is used in only a few institutions. The indirect methods are more widely employed for clinical work and physiological experimentation.

Indirect Methods

There are two general indirect methods for the study of metabolism, the "closed circuit" and the "open circuit" types.

The Closed Circuit Method.—In this the expired air is passed through bottles containing suitable reagents for the absorption of water and carbon dioxide, and the amount of oxygen used is determined from the amount added during the experiment to keep the total

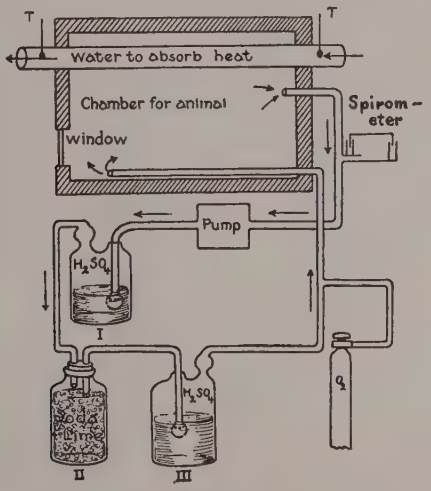

Fig. 274.—Diagram of Atwater-Benedict respiration calorimeter. As the animal uses up the O_2 the total volume of air decreases. This change is indicated by the spirometer, and a corresponding amount of O_2 is delivered from the weighed O_2 cylinder. The increase in weight of bottles II and III gives the CO_2; that of I, the water vapor.

volume of the system unchanged. This method may be used with a calorimeter (Fig. 274) in which case the results of the indirect method may be compared with those of the direct. The chamber is connected with a closed system of tubes through which air is passed by a pump. Outside the chamber the air passes through a spirometer, a bottle of concentrated sulfuric acid, a bottle of soda lime, and a second bottle of sulfuric acid. The first sulfuric acid absorbs water vapor in the air coming from the chamber, the soda lime takes out the carbon dioxide, and the second sulfuric acid takes up the water produced by the reaction between the soda lime and the carbon dioxide. The amounts of water and carbon dioxide given off by the subject are found by weighing these bottles before and after the subject has been placed in the chamber. During the experiment oxygen is admitted to the system from a side tube at such a rate that the amount used by the subject is exactly replaced. The quantity of oxygen taken up by the subject may be determined by weighing the cylinder from which it comes before and after the experiment or by passing the gas through a sensitive meter placed between the oxygen tank and the tubing of the system.

To avoid the necessity of building a closed cabinet for these determinations, numerous devices, such as the Benedict helmet, masks, mouthpieces and nosepieces, have been designed for connection of the subject with the apparatus. These contrivances are also used with the open circuit method.

The Open Circuit Method.—In this the subject breathes through a valve system so arranged that it separates the inspired from the expired air. The volume of expired air is measured by collecting it in a spirometer (Tissot method) or a rubber bag (Douglas method). A sample of the expired air is analyzed for carbon dioxide and oxygen and by suitable calculation the total respiratory exchange is obtained.

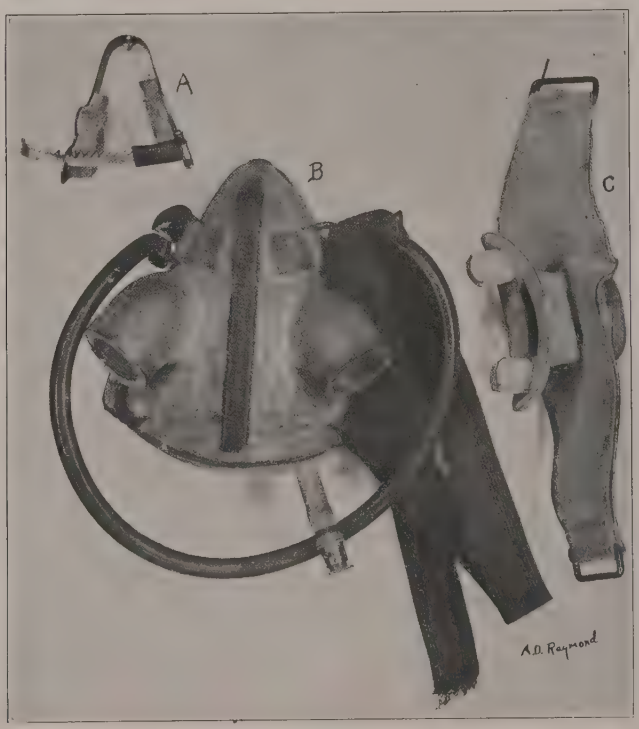

Fig. 275.—*A*, Nose clip; *B*, Face mask; *C*, Mouthpiece.

Description and Purposes of the Parts of the Apparatus Used: Valves, Mouthpieces, and Masks.—The various devices for connecting the subject with the apparatus are shown in Fig. 275. The mouthpiece (*C*) has a rubber flange, which fits between the subject's cheeks and teeth, and two soft rubber projections which are to be held between the teeth. The nose clip (*A*) is used to avoid any loss of air through this passage. Some individuals find it very difficult to breathe through a mouthpiece. Numerous types of masks and the Benedict helmet[46] are useful in such cases. Masks have the advantage that they allow the subject to breathe normally through the nose, but possess the disadvantages of being subject to leaks and of becoming uncomfortable during prolonged experiments. A diagram of the mask used by Bailey[60] and its connections with a spirometer are shown in Fig. 276.

The types of valves which have been designed to separate the inspired from the expired air are numerous. Such a valve should have low resistance to the passage of air so that the

subject will not experience a feeling of pressure. Further, the dead space should be small to avoid accumulation of carbon dioxide. The valve used in the Johns Hopkins Physiological Laboratory is a modification of the Lovén type; it is shown in Fig. 277. On inspiration the rubber membrane is pulled away from the metal ring, *A*, while the other membrane is pulled against a similar ring, *B*, on the other side. This arrangement allows air to pass from the atmosphere into the valve during inspiration and prevents atmospheric air from passing out through the expiratory side of the valve. On expiration the rubber membrane is pushed away from *B* while on the inspiratory side the membrane is brought into close contact with *A*. In this manner the inspired and expired airs are separated. The disadvantage of these valves is that the rubber may stick to the metal and break easily. Flutter valves such as are used in gas masks are more satisfactory for long experiments and for clinical use.

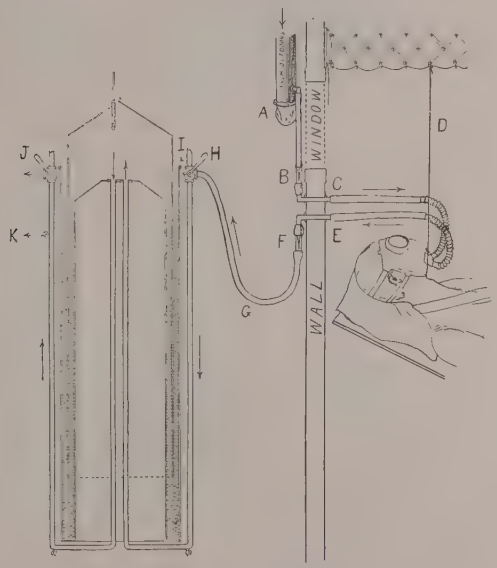

Fig. 276.—Apparatus for the determination of the basal metabolism. The subject, lying at rest on a cot and wearing a face mask, is separated by a wall and window from the spirometer. *C* and *E* are pipes leading from the mask to outside air and spirometer, respectively; *B* and *F* are flutter valves which direct inspiratory air to mask from outside and expiratory air to spirometer from mask. The spirometer consists of a bell which is arranged to rise freely as the expired air is collected under it. The entire dead space of the apparatus can be flushed out with expired air by allowing it to escape through the valve *J*. On closing this valve the expired air is caught in the spirometer bell. *H* is a valve which permits expired air to escape through *I*, a vent. (From Bailey: J. Lab. and Clin. Med. **6**: 657, 1921.)

The Collection of Expired Air.—The expired air may be collected in a spirometer or in a Douglas bag[75] or it may be measured directly by passage through a gas meter. Since ordinary gas meters are not sensitive enough to follow the sudden change in flow occurring at expiration, special meters have been designed which record and measure such changes with sufficient accuracy. Nevertheless the most practical method is to collect the expired air in a spirometer. A diagrammatic representation of a spirometer is given in Fig. 276. In the design of this apparatus special attention should be given to the freedom of movement of the bell, for its rise must be directly proportional to any increase in volume. The dead space must be small so that the amount of gas present at the beginning of the experiment does not influence the final composition of the gases in the spirometer. This factor may be minimized by washing out the spirometer with expired air before each experiment. The necessary compensation for the change in the buoyancy effect as the bell changes its position in the water is accomplished by attaching a weight to a spiral so that the pull on the bell varies with its

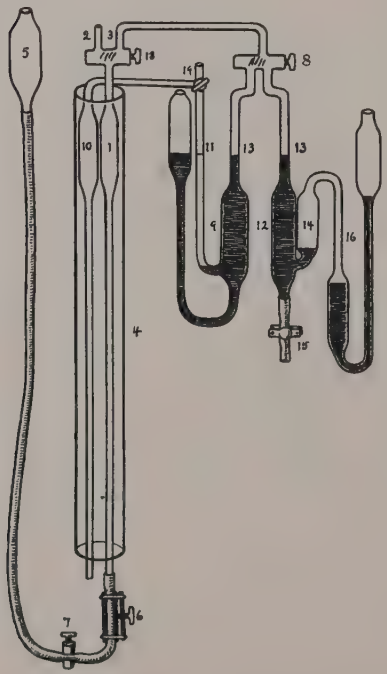

Fig. 278.—Haldane gas analysis apparatus. *1*, calibrated burette; *2*, side tube for admission of sample; *3*, connection to KOH and pyrogallate reservoirs; *4*, water jacket for temperature control; *5*, mercury reservoir; *6*, clamp for fine adjustment of mercury column; *7*, stopcock; *8*, stopcock for directing gas into KOH or pyrogallate reservoir; *9*, KOH reservoir; *10*, compensating burette; *11*, mark on tube for fixing volume of gas in compensating burette; *13*, marks on tube for volume control in KOH and pyrogallate reservoirs; *12*, *14*, *15*, *16*, pyrogallate reservoir.

position. Spirometers may be calibrated by passing air through an accurate meter into the bell, or by measurement of the circumference and height and calculating the volume.

One disadvantage of the spirometer is that it is not portable. The Douglas bag[75] was designed for use in experiments involving exercise such as walking or running. The bag is made of rubber, covered with canvas, and usually has a capacity of about one hundred liters. After collection of the gas its volume is measured by passing it from the bag through a meter. The disadvantages of the Douglas bag are that it wears out quickly and becomes permeable to carbon dioxide and oxygen. A slow leakage of gas may not be of significance when determinations are made immediately after a collection, but if the gas is allowed to remain in the bag for several hours serious error may result. The bag should be rolled tightly before and after each analysis.

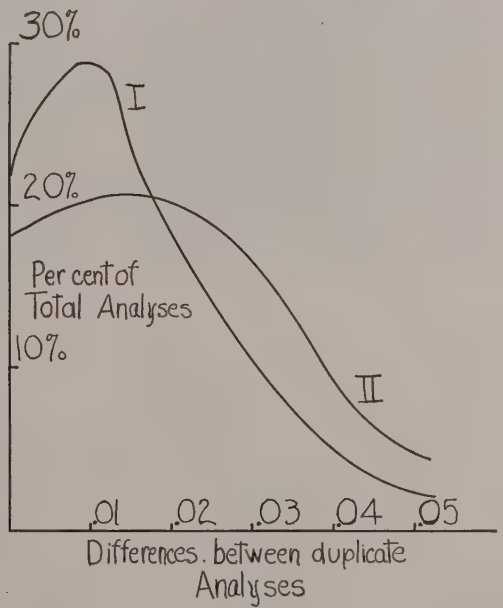

Fig. 279.—Deviation between duplicate analyses in terms of CO_2 (I) and O_2 (II) percentages plotted against the per cent of the total number of analyses. (From Gemmill: Am. J. Physiol. 98: 135, 1931.)

Gas Analysis.—After a period of collection a sample of expired air is analyzed. The type of gas analyzer most generally used is some modification of the Haldane apparatus (Fig. 278). This consists of a calibrated burette attached by stopcocks to two reservoirs, one containing a solution of KOH for the absorption of CO_2 and the other an alkaline pyrogallate solution for the absorption of O_2. A control tube is connected to the alkali reservoir to compensate for any changes in temperature or barometric pressure. To begin an analysis, gas is transferred from a sampling tube to the apparatus and its volume measured. The gas is then passed through the KOH solution several times and returned to the calibrated burette where its volume is again measured. The change in volume gives the amount of CO_2 in the original sample of gas. In a similar manner the O_2 is taken up in the pyrogallate solution and the resulting loss in volume determined. No analysis of expired air should ever be made without first testing the apparatus by analyzing a sample of atmospheric air. The results of duplicate analyses should agree within 0.03 per cent. Variations found in a series of 240 analyses are shown in Fig. 279. Exact details and practical suggestions for carrying out gas analyses may be found in the book by Peters and Van Slyke.[61]

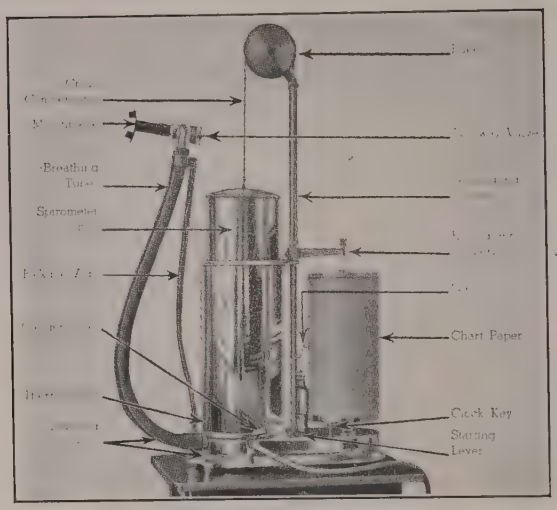

Fig. 280.—The Benedict-Roth metabolism apparatus. (Courtesy of Warren E. Collins, Inc., Boston.)

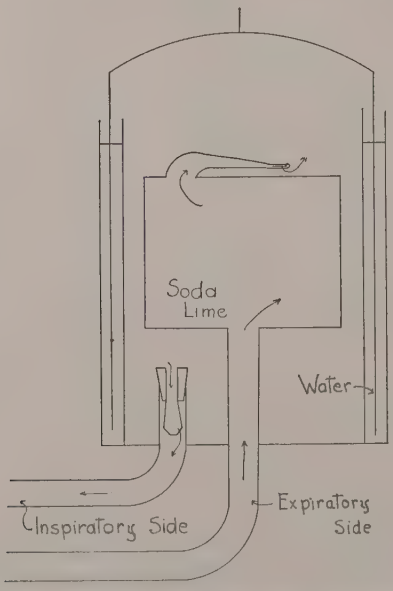

Fig. 281.—Diagram of the connections in the spirometer of the Benedict-Roth apparatus.

Clinical Methods.—The methods described above require considerable training and experience before satisfactory results are obtainable. For this reason simpler methods have been devised for clinical work. A type of apparatus widely used in hospitals and by physicians in their offices is shown in Fig. 280. It consists of a closed circuit from which oxygen is removed by the subject's lungs and in which the carbon dioxide of the expired air is taken up by passage over soda lime (Fig. 281). Before beginning an experiment an amount of oxygen is admitted sufficient to raise the spirometer bell to the zero mark on a vertical scale calibrated in terms of volume. The inspirations and expirations of the subject are reflected in alternate downward and upward movements of the spirometer bell, but these occur at a steadily decreasing height as the total volume of the system diminishes with the consumption of oxygen. The difference in the height of the bell at the beginning and the end of the run (usually six minutes) represents the volume of oxygen used in the interval. This is then corrected for aqueous tension and reduced to standard temperature and pressure. A graphic record of the breathing movements along a base line, which slants because of the fall in volume in the system, is usually made on graph paper from which the rate of oxygen consumption can be converted to Calories per hour. This method has several disadvantages. The assumption is made that the respiratory quotient is normal (0.82), and it is on this basis that the Calories are calculated. Such a procedure, however, does not introduce a large error, for the caloric value of one liter of oxygen varies but little for respiratory quotients between 0.70 and 1.00. A more serious criticism is that the accuracy of the determination depends on the regular breathing of the patient. It is very difficult for some individuals to breathe normally through a mouthpiece and valves, but with repeated trials a smooth slope is usually obtained for calculating the change in volume due to the oxygen consumption. With an apparatus of this type Benedict obtained values of 247, 245, and 241 ml. of oxygen in three successive trials on the same individual.

It is difficult to check the accuracy of the indirect methods. In the direct method alcohol is burned in the calorimeter and the heat produced is compared with the theoretical value calculated from the heat of combustion. Benedict[43] has devised a special alcohol combustion apparatus for testing the indirect methods. If this apparatus is not used, repeated tests carried out on a trained subject will give a good indication of the accuracy of the apparatus.

A critical comparison of the various indirect methods was made by Carpenter.[50] He concluded that the Benedict apparatus has two advantages: rapidity of operation and the fact that it gives a graphic record of the metabolism. The Tissot spirometric apparatus is not difficult to use and the results obtained with it are reliable. The Douglas bag method must be carefully controlled by testing the bags for diffusion of gases. Its chief advantage is the portability of the apparatus. For one who has mastered gas analysis, the Tissot spirometer is the apparatus of choice. If two spirometers are available they may be connected by valves so that one is filling while the other is being emptied. This permits continuous observations of metabolism over long periods of time (Gemmill[79]).

THE RESPIRATORY QUOTIENT

The respiratory quotient (R. Q.) is defined as the ratio of the *volume* of carbon dioxide expired to the *volume* of oxygen consumed during the same period of time. It has long been known that among animals this ratio varies to some extent with the food. The quantity of oxygen required and the amount of carbon dioxide produced in the combustion of food, either within or outside the body, depends on the chemical composition of the material. Therefore the respiratory quotient for any individual foodstuff may be determined from the equation representing its oxidative breakdown to the final products. Since equal volumes of gases at the same temperature and pressure contain the same number of molecules (Law of Avagadro), it is not necessary, in making this determination, to convert the number of molecules of the two gases into volumes. The following examples illustrating the method of calculating the respiratory quotient are taken from Lusk's *Science of Nutrition*.[60]

1. **Carbohydrate.**—The general formula for this class of foodstuffs may be written $(CH_2O)_n$ from which it is plain that hydrogen and oxygen are always

present in the proportions to form water. Therefore on combustion extramolecular oxygen is required only for the formation of carbon dioxide. That the respiratory quotient will be unity is evident from the following equation:

$$\underset{\text{(glucose)}}{C_6H_{12}O_6} + 6O_2 = 6CO_2 + 6H_2O$$

$$\text{R. Q.} = \frac{6 \text{ volumes } CO_2}{6 \text{ volumes } O_2} = 1.00$$

2. **Fat.**—In the oxidation of this substance, extramolecular oxygen is required not only for the oxidation of carbon but also for the oxidation of hydrogen. For this reason the respiratory quotient will be less than unity. If we take as an example tripalmitin, $C_{51}H_{98}O_6$, this fact becomes evident from the following equation:

$$2C_{51}H_{98}O_6 + 145\ O_2 = 102\ CO_2 + 98H_2O$$

$$\text{R. Q.} = \frac{102 \text{ volumes } CO_2}{145 \text{ volumes } O_2} = 0.703$$

Food fats, which are composed chiefly of the glycerides of palmitic, stearic, and oleic acids, give a quotient of 0.706.

3. **Protein.**—It is more difficult to calculate the respiratory quotient of the combustion of protein in the body because some of the oxygen and carbon of the constituent amino acids remains combined with nitrogen and is excreted as nitrogenous compounds of the urine and feces. Determinations have been based on accurate analyses of the ingested protein and of the excreta. Table XXXII gives the figures reported by Loewy:

TABLE XXXII

	ELEMENTS IN GRAMS				
	C	H	O	N	S
100 grams meat protein contain	52.38	7.270	22.68	16.65	1.02
Elimination:					
In the urine	9.406	2.663	14.099	16.28	1.02
In the feces	1.471	0.212	0.889	0.37	
Leaving for respiratory processes	41.50	4.40	7.69		
Intramolecular water		0.961	7.69		
For oxidation	41.50	3.439			

(From Lusk[60] after Loewy)

The quantities of carbon and hydrogen involved in oxidative processes require 138.18 grams of oxygen; 152.17 grams of carbon dioxide are produced. Converting these quantities into volumes* we find that the ratio for protein is:

$$\text{R. Q.} = \frac{77.52 \text{ liters } CO_2}{96.70 \text{ liters } O_2} = 0.802$$

4. **Other Substances.**—In a similar manner respiratory quotients have been calculated for the oxidation of a number of compounds of biological significance.

The actual calculation of the *total* and *nonprotein* respiratory quotients in a human subject is given on pages 736-739.

Significance of the Respiratory Quotient.—From the foregoing discussion it might seem that the determination of the respiratory quotient furnishes in-

*Conversion is carried out on the basis of the fact that at N. T. P. 1 gram of O_2 occupies 0.6998 liter, 1 gram of CO_2 0.5094 liter.

TABLE XXXIII

RESPIRATORY QUOTIENTS CALCULATED FROM CHEMICAL EQUATIONS FOR OXIDATION (RICHARDSON[62])

SUBSTANCE	R. Q.
Glycerol	0.86
Glyceric aldehyde	1.00
β-hydroxybutyric acid	0.89
Acetoacetic acid	1.00
Acetone	0.75
Lactic acid	1.00
Pyruvic acid	1.20
Alcohol	0.667

formation concerning the kind of foodstuff being metabolized. Such indeed is the general impression. Unfortunately experimental evidence has not given this idea complete support, especially when the metabolic changes have been examined over short periods of time. The difficulty arises from the fact that the cells of the body are able not only to oxidize various foodstuffs concurrently but also to convert one food material into another.

Theoretically, the ingestion of glucose should raise the respiratory quotient to 1.00 if glucose alone is oxidized. Benedict and Higgins[70] fed various amounts of sugar to fasting subjects. After the subject had ingested six hundred grams of glucose in one day, the highest respiratory quotient which they observed was 0.87. Cathcart and Markowitz[73] studied the change in the respiratory quotient and the increase in metabolism following the ingestion of various sugars. Glucose and maltose raised the metabolism, but the respiratory quotient did not reach unity. On the other hand, cane sugar raised the quotient to 1.00, but did not change the metabolism. Krogh and Lindhard[83] fed a group of men high carbohydrate or high fat diets over periods of two or more days. They observed that the respiratory quotient rose on a carbohydrate diet and fell on a fat diet, but it did not reach the theoretical levels, 1.00 and 0.71, respectively. Higgins[81] determined the quotient before and after ingestion of alcohol. Although the theoretical quotient for the oxidation of this substance is 0.667, the lowest figure obtained experimentally was 0.775. These facts illustrate the point that, even when the subject is on a diet consisting of a single chemically pure substance, oxidation of that substance to the exclusion of all others never occurs. Another complication is the transformation of food materials from one form to another. The conversion of carbohydrate to fat (which certainly occurs) tends to raise the quotient above unity, while the reverse process (which probably occurs) tends to lower it below 0.71. Soskin[91] has presented several lines of evidence which show that a quotient of 0.70 does not indicate inability to oxidize carbohydrate. His latest results were obtained in a study of the disappearance of sugar from the blood of fasting and fed dogs after evisceration. The fall in blood sugar followed the same curve in the fasting as in the fed dogs. He concluded that the utilization of sugar is not impaired by fasting and that the low respiratory quotients observed under such conditions are due to increased formation of carbohydrate and not to an exclusive oxidation of fat. This problem will be discussed more fully in Chapter L. The splitting off of CO_2 from acids or the taking up of oxygen by hydrogen released in the partial oxidation of a compound are reactions which may further complicate the calculation of the respiratory quotient.

Other things than oxidative processes exert profound effects on the value of the respiratory quotient. These may be summarized as follows (Richardson[62]):

A. The respiratory quotient is increased by:
   1. Hyperventilation
   2. Acid formation
      a. Lactic acid (muscular exercise; convulsions; asphyxia; adrenalin)
      b. Keto-acids (diabetes; carbohydrate starvation)
   3. Acid retention (as in nephritis)

B. The respiratory quotient is decreased by:
   1. Hypoventilation
   2. Acid removal (by oxidation, excretion of free acid, synthesis, loss of HCl from stomach by vomiting)
   3. Alkalosis produced by alkali therapy.

In view of the evidence presented above the respiratory quotient should not be regarded as an exact indicator of specific metabolic processes, but as a resultant of all the changes in the body which require oxygen and lead to excretion of carbon dioxide. In metabolism experiments, however, it is necessary to convert liters of oxygen into Calories. Zuntz and Schumburg constructed tables (for their latest modification see Lusk[84]) which give, for different respiratory quotients, the caloric value of a liter of oxygen. The assumption underlying these figures is that a nonprotein respiratory quotient (see page 739) of 1.00 indicates an exclusive oxidation of carbohydrate while one of 0.71 signifies an oxidation of fat alone, and any quotient between these two values is the resultant of the burning of a mixture of fat and carbohydrate in definite proportions. The situation has been shown to be more complex than this simple theory demands. The question arises as to what should be used for the conversion of liters of oxygen to calories. The answer is that it does not make much difference. At a respiratory quotient of 0.71 the number of Calories produced per liter of oxygen used is only about 6 per cent less than when the respiratory quotient is 1.00. In the following section this fact is illustrated by an example (page 739).

The Calculations

The calculations required in the determination of the energy exchange by the indirect method are given in the following example.

Analysis of Expired Air.—

Carbon dioxide:

1st reading of burette	20.00
2nd reading (after absorption)	19.20
CO_2 absorbed	0.80

$$\frac{0.80}{20} \times 100 = 4.0\%\ CO_2 \text{ in expired air}$$

Oxygen:

2nd reading of burette	19.20
3rd reading (after absorption)	15.90
O_2 absorbed	3.30

$$\frac{3.30}{20} \times 100 = 16.5\%\ O_2 \text{ in expired air.}$$

Determination of Respiratory Quotient.—

O_2 in atmospheric air = 20.94%
$O_2 + CO_2$ in expired air (16.5 + 4.0) = 20.50%
N_2 in atmospheric air = 100 − 20.94 = 79.06%
N_2 in expired air = 100 − 20.50 = 79.50%

The change in the percentage of nitrogen, a gas which is inert in the body, means that there is a difference in the volumes of the inspired and expired air. This is due to the fact that during the experiment the carbon dioxide given off is less than the oxygen taken up. A correction must be made for this difference between the total volume of the inspired and expired air. Multiplying the ratio of the percentage of oxygen to the percentage of nitrogen in atmospheric air by the percentage of nitrogen in the expired air gives a corrected value for the oxygen percentage of the inspired air. The actual calculation, made on the basis of the figures appearing above, will make this clearer:

$$20.94 : 79.06 = x : 79.5$$

$$x = \frac{20.94}{79.06} \times 79.5 = 21.07$$

Since the ratio $\frac{20.94}{79.06}$ is constant for each experiment, a factor, 0.265, may be used in the multiplication. The calculation can be simplified by using the accompanying abbreviated table (Table XXXIV) which gives the O_2 figure corresponding to the various percentages of N_2 in the expired air.

TABLE XXXIV

THE PERCENTAGE OF OXYGEN WHICH IS EQUIVALENT TO THE NITROGEN FOUND IN THE EXPIRED AIR

To obtain the nitrogen in the expired air, add the percentages of CO_2 and O_2 found and subtract the sum from 100. The table gives the percentage for O_2 corresponding to this figure:

% N_2	78.7	78.8	78.9	79.0	79.1	79.2	79.3	79.4	79.5
% O_2	20.85	20.88	20.91	20.93	20.96	20.99	21.01	21.04	21.07

Having reduced both percentages to the same basis, a simple subtraction gives the percentages of carbon dioxide excreted and of oxygen used during the experiment:

Percentage of O_2 absorbed = 21.07 − 16.50 = 4.57%
Percentage of CO_2 excreted = 4.00 − 0.03 (CO_2 in inspired air) = 3.97%

Since the amount of CO_2 in the inspired air is so small it is not necessary to make a correction as in the case of the oxygen consumption. The respiratory quotient, the ratio of the volume of CO_2 given off to the volume of oxygen used, is therefore,

$$\frac{3.97}{4.57} = 0.87$$

Total Gas Exchange.—Let us suppose that the volume of air expired in fifteen minutes into the Tissot spirometer is 100 liters at 20° C. and 747 mm. Hg (brass-scale barometer). This volume must be corrected to give the volume of dry air at 0° C. and 760 mm. Hg. To do this, the following corrections must be made:

1. The pressure due to water vapor must be subtracted from the observed barometric pressure (Table XXXV gives these corrections at various temperatures).

TABLE XXXV

TENSION OF AQUEOUS VAPOR IN MILLIMETERS OF MERCURY

To obtain the dry barometric pressure, subtract the mm. Hg corresponding to the temperature of the air from the barometric pressure at the time of the experiment:

Temp.	15°	16°	17°	18°	19°	20°	21°	22°	23°	24°	25°
Mm.	12.79	13.64	14.54	15.49	16.49	17.55	18.67	19.84	21.09	22.40	23.78

2. The barometric readings must be corrected for temperature as the barometer alters its length with changes in temperature (Table XXXVI).

TABLE XXXVI

TEMPERATURE CORRECTIONS TO REDUCE READINGS OF A MERCURIAL BAROMETER WITH A BRASS SCALE TO 0° C.

Subtract the appropriate quantity as found in the table from the height of the barometer. The table is for a barometer with a brass scale; the values are a little lower (about 0.2 mm.) than for the glass scale. The corrections for intermediate temperatures can be approximated by interpolation:

Temp. °C.	740 mm.	750 mm.	760 mm.	770 mm.	780 mm.
15	1.81	1.83	1.86	1.88	1.91
20	2.41	2.44	2.47	2.51	2.54
25	3.01	3.05	3.09	3.13	3.17

In this experiment, with the expired air and the barometer at 20°, the correction for the vapor tension is 17.55 mm., for the expansion of the brass scale of the barometer 2.43 mm. Therefore the corrected barometric pressure is:

$$747 - (17.55 + 2.43) = 727.02 \text{ mm.}$$

To correct the volume to 0° C. and 760 mm. pressure, the following formula may be used:

$$V\ (0° \text{ and } 760 \text{ mm.}) = \frac{P\ V}{(1 + 0.00367\ t)\ 760},$$

where P is the corrected barometric pressure, V the observed volume, t the temperature and 0.00367 the coefficient of expansion of gas. In practice, however, tables are used which give this factor for various pressures and temperatures. Carpenter[51] has published such

TABLE XXXVII

FACTORS FOR REDUCING GASEOUS VOLUMES TO NORMAL TEMPERATURE AND PRESSURE*

The observed volume, when multiplied by the factor corresponding to the temperature and corrected pressure, will give the volume of the expired air reduced to 0° and 760 mm.

Mm.	15°	16°	17°	18°	19°	20°	21°	22°	23°
750	0.919	0.915	0.911	0.907	0.902	0.898	0.893	0.889	0.884
760	0.932	0.928	0.923	0.919	0.915	0.910	0.906	0.901	0.897
770	0.944	0.940	0.936	0.931	0.927	0.922	0.918	0.913	0.909

tables (Table XXXVII) together with others which aid in the calculation of metabolic rate. The calculated factor in this experiment is 0.892. Therefore,

$0.892 \times 100 = 89.20$ liters of dry air expired corrected to 0° C. and 760 mm. Hg.

The amount of oxygen consumed in fifteen minutes is

$$89.20 \times 4.57 = 4.08 \text{ liters of } O_2$$

and the amount of carbon dioxide given off is

$$89.20 \times 3.97 = 3.54 \text{ liters } CO_2$$

The Caloric Value Calculated From the Respiratory Metabolism.—The nonprotein respiratory quotient is calculated by deducting from the O_2 and CO_2 values of the total respiratory exchange the O_2 and CO_2 involved in the protein metabolism. In brief experiments it is impossible to measure the urinary nitrogen. Therefore, an assumption must be made on the

*These factors are obtained by the formula, $\frac{1}{1 + 0.00367\ t} \times \frac{P - e}{760}$, where t is the temperature, P the barometric pressure after scale correction and e the pressure of aqueous vapor at temperature t.

basis of the amount of nitrogen excreted in twenty-four hours. Suppose, for example, that 14.4 grams of nitrogen are excreted in that time; the average hourly output is 0.6 grams. It has been determined that, for every gram of urinary nitrogen derived from protein, 8.49 grams of O_2 are used and 9.35 grams of CO_2 are eliminated. Using these values and the factors for converting grams of CO_2 and O_2 into liters (1 gram CO_2 = 0.5094 liters and 1 gram O_2 = 0.6998 liters), the amount of CO_2 given off and O_2 required for the oxidation of protein may be calculated as follows:

$$0.6 \times 9.35 \times 0.5094 = 2.86 \text{ liters of } CO_2 \text{ per hour}$$
$$0.6 \times 8.49 \times 0.6998 = 3.56 \text{ liters of } O_2 \text{ per hour}$$

Taking the total amount of oxygen used and of carbon dioxide given off per hour and subtracting the values obtained for the oxidation of protein, the amounts of the respiratory gases involved in the nonprotein oxidation are obtained as follows:

$$(4 \times 3.54) - 2.86 = 11.30 \text{ liters of } CO_2 \text{ per hour}$$
$$(4 \times 4.08) - 3.56 = 12.76 \text{ liters of } O_2 \text{ per hour}$$

Thus the nonprotein respiratory quotient is $\frac{11.30}{12.76}$ or 0.88.

TABLE XXXVIII

CALORIC VALUE OF 1 LITER OF OXYGEN AT VARIOUS RESPIRATORY QUOTIENTS*

R. Q.	0.707	0.75	0.80	0.85	0.90	0.95	1.00
Calories	4.686	4.739	4.801	4.862	4.924	4.985	5.047

From Table XXXVIII it is seen that at a quotient of 0.87 one liter of oxygen is equivalent to 4.887 Calories; at a respiratory quotient of 0.88 this value is 4.899 Calories. If the respiratory quotient were not determined but assumed to be 0.82, the value would be 4.825. Using these values and the fact that 1 gram of urinary nitrogen is equivalent to 26.51 Calories, the results shown in Table XXXIX are obtained:

TABLE XXXIX

RESPIRATORY QUOTIENT		CALORIES PER HOUR	CALORIES PER SQ. METER OF BODY SURFACE PER HOUR	BASAL METABOLIC RATE
Total	0.87	79.76	39.88	+1.0
Nonprotein	0.88	78.42	39.21	−0.8
Assumed	0.82	78.82	39.41	−0.2

CALCULATION OF THE BASAL METABOLIC RATE

For reasons to be discussed it is customary to calculate the metabolism on the basis of Calories per square meter of body surface per hour and to compare this value with a normal standard. Assuming that a subject weighs 80 kilograms and is 180 centimeters in height, his surface area, as obtained from the chart constructed by DuBois (Fig. 283), is 2.0 square meters. From the table of standard metabolic rates (Table XL), it is found that a man between twenty and thirty years of age should have a metabolism of 39.5 Calories per square meter of body surface per hour. The observed value is then divided by the factor and expressed as a percentage, from which one hundred is subtracted algebraically to give the metabolic rate. There is practically no difference between the metabolic rates obtained from the three determinations in

*Calories $= 4.686 + \frac{(\text{R. Q.} - 0.707) \times 0.361}{0.293}$ (Lusk[60])

which different respiratory quotients are employed (see Table XXXIX). Since normal individuals vary ± 15 per cent from the standard, the variation due to the method of calculation is very small. It would be well, especially in short

TABLE XL

CALORIES PER SQUARE METER OF BODY-SURFACE (HEIGHT-WEIGHT FORMULA) PER HOUR (Aub and DuBois Standards)

AGE (YEARS)	MALES	FEMALES
14 to 16	46.0	43.0
16 to 18	43.0	40.0
18 to 20	41.0	38.0
20 to 30	39.5	37.0
30 to 40	39.5	36.5
40 to 50	38.5	36.0
50 to 60	37.5	35.0
60 to 70	36.5	34.0
70 to 80	35.5	33.0

determinations, to disregard the Zuntz-Schumburg tables with their implication that a given respiratory quotient means the oxidation of a definite mixture of carbohydrate and fat. It is preferable to assume an average caloric value for this determination.

Comparison of Direct and Indirect Methods

It was necessary to discuss methods and the respiratory quotient before continuing the consideration of the application of the first law of thermodynamics to biological systems. According to this law the heat produced by the combustion of food material should be equivalent to the heat liberated by the subject at rest. Rubner[89] in 1894 determined by means of a calorimeter the heat produced by dogs and at the same time measured the carbon dioxide expired and the nitrogen excreted in the urine. Assuming that under fasting conditions a dog oxidizes only protein and fat, he was able to calculate the amount of food material burned in twenty-four hours. By comparing the heat available from the oxidation of this material with the actual amount of heat liberated by the animal during the same period of time, he found close agreement between these two observations on fasting dogs and also on dogs which were fed meat and fat. His results are given in Table XLI.

TABLE XLI

COMPARISON OF HEAT CALCULATED FROM GASEOUS EXCHANGE WITH HEAT ACTUALLY PRODUCED (Rubner[89])

FOOD	DAYS	HEAT CALCULATED CALORIES	HEAT DETERMINED CALORIES
Starvation	5	1296.3	1305.2
	2	1091.2	1056.6
Fat	5	1510.1	1495.3
	6	2249.8	2276.9
Meat	7	4780.8	4769.3

From these results Rubner was able to compare the heat produced during the oxidation of one gram of protein or fat in the body with that liberated when the same amount of material was burned in a bomb calorimeter (Table XLII).

TABLE XLII

A COMPARISON OF THE HEATS OF COMBUSTION OF ONE GRAM OF FOOD MATERIAL IN THE ANIMAL BODY AND IN A CALORIMETER

FOOD	HEATS OF COMBUSTION OF ONE GRAM IN CALORIES	
	IN ANIMAL BODY	IN THOMPSON CALORIMETER
Meat	4.059	4.000
Meat	4.007	4.000
Fat	9.334	9.423
Fat	9.353	9.423

Rubner's work was continued by Atwater and Benedict in this country. With the aid of Rosa, Atwater[67] constructed a calorimeter in which both the heat production and the respiratory metabolism of a human being could be measured. Some of their results are given in Table XLIII.

TABLE XLIII

COMPARISON OF INDIRECT AND DIRECT CALORIMETRY APPLIED TO HUMAN SUBJECTS AT REST AND AT WORK (Atwater[67])

TYPE OF EXPERIMENT	NUMBER OF EXPERIMENTAL DAYS	AVERAGE CALORIES PER 24 HOURS	
		INDIRECT CALORIMETRY	DIRECT CALORIMETRY
Rest	41	2246	2246
Work	66	4682	4676

During a series of feeding experiments on dogs Murlin and Lusk[86] also compared the indirect with the direct method of calorimetry. Their results are summarized in Table XLIV. Coleman and Dubois[74] extended this work to

TABLE XLIV

A COMPARISON OF THE DIRECT AND INDIRECT METHODS OF CALORIMETRY (Murlin and Lusk[86])

DOG	NUMBER OF EXPERIMENTS	METHOD		DIFFERENCE		NUMBER OF EXPERIMENTS IN WHICH ERROR WAS	
		INDIRECT (CALORIES CALCULATED)	DIRECT (CALORIES MEASURED)	CALORIES	%	UNDER 2%	OVER 2%
III	10	996.71	975.05	21.66	2.2	5	5
XIV	22	2244.20	2230.18	14.02	0.6	14	8

a study of typhoid fever patients and found that while the total Calories determined for all their subjects by the two methods checked very closely, the results of individual experiments deviated as much as 17 per cent.

From the examples given above it is apparent that the caloric content of food can be compared with the actual amount of heat liberated when the body metabolizes this food. This fact proves that the first law of thermodynamics holds for such a complex biological system as the human body. The slight deviations between the two quantities are probably due to the use of the Zuntz-Schumburg tables for the calculation of the caloric value of oxygen. Poulton[87] has critically examined the results of Benedict and Carpenter and has found that the percentage differences between the heat produced as calculated from the oxygen consumption and the actual heat as measured by the calorimeter

varied with the respiratory quotient. The graphic summary of this comparison is given in Fig. 282 which shows that the calculated heat production is too high for the lower respiratory quotients and too low for the higher ones. The variations are greater than the analytical error incurred in measuring the heat production and the respiratory quotient of the combustion of alcohol. Poulton suggests that these variations are due to fundamental errors in the Zuntz-Schumburg tables, since the latter do not allow for the conversion of carbohydrate to fat at the higher quotients nor for a possible transformation of fat to carbohydrate at the lower. The agreement between the calculated and the observed heat productions is at its best for the range of respiratory quotients usually found in basal metabolic tests. It is not surprising that relatively poor agreements are observed under abnormal conditions. For example, Benedict

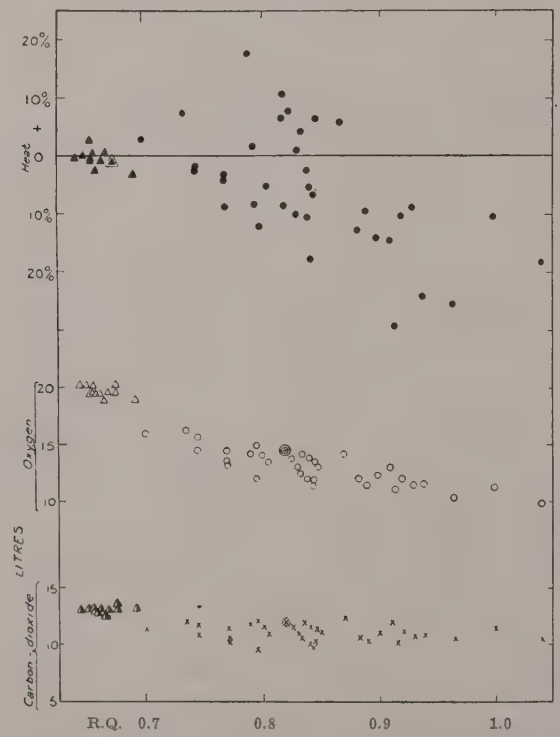

Fig. 282.—Discrepancies between the results of direct and indirect calorimetry at various respiratory quotients. The abscissae represent the respiratory quotients, and the horizontal line at zero, in the upper part of the figure, the measured heats (direct calorimetry). Satisfactory agreement between the two methods would require that the points lie more or less evenly above and below this line throughout the range of respiratory quotients.

● = the difference between the calculated and measured heats expressed as percentages of the latter.

▲ = values obtained from burning alcohol in the calorimeter.

▲ = carbon dioxide } alcohol checks
△ = oxygen }

○ = oxygen } values during the first day of fasting calculated per hour.
× = carbon dioxide } Subjects at rest.

The measured heat has been corrected both for change in body weight and body temperature. (From Poulton: Proc. Roy. Soc. Med. 26: 1591, 1933.)

and Carpenter[48] found that direct and indirect calorimetry do not necessarily agree when excessive amounts of carbohydrate are ingested.

Second Law of Thermodynamics.—Heats of combustion which are used at the present time in metabolic experiments do not give any information concerning that part of the heat, the free energy, which is available for work. Free energy may be greater or less than the heat of combustion. If greater than the heat of combustion, the process may be improved so that more work may be obtained from the system. If the free energy is less, even if all of this energy may be converted into work, there is still additional energy which is unavailable for work. These facts have been incorporated into the second law of thermodynamics which deals with this loss of availability of energy for external work. The application of this law enables the observer to decide whether a certain reaction can take place and to determine the maximal amount of work that may be obtained from the system. It tells nothing of the speed of the reaction nor of the mechanisms involved. At the present time, free energy data can be applied only to simple systems, such as enzyme reactions or bacterial metabolism. The application of free energy data to metabolic processes will continue as our knowledge of the data and of the metabolic changes increases. It may be that in this century the use of the second law of thermodynamics will lead the way to an advance in our knowledge of metabolic processes, comparable to that which resulted in the application of the first law of thermodynamics to biological problems in the last century.

BASAL METABOLISM

In order that a *comparison* of the metabolic activity of individuals and species may be made, certain conditions have been selected for its determination. DuBois[54] lists the many factors which influence metabolism as follows:

A. Factors excluded in all basal tests on normal controls:

1. Muscular movements during the test
2. Recent muscular exertion (within a half to one hour)
3. Food within twelve or fourteen hours
4. Strong emotions, noises, discomforts
5. Extremes of environmental temperature
6. Disease

B. Factors taken into account in the interpretation of determinations of basal metabolism:

Age	Athletic training
Sex	Climate
Weight and height	Altitude
Surface area	Sleep
Under- or overnutrition	Body temperature

C. Additional factors which may or may not be of importance:

Occupation	Vigorous exercise or emotion
Race	on day before the test
Previous diet	Novelty of the situation
Menstruation	Time of year

The three factors that have the most to do with determining the level of metabolism are muscular activity, extremes of external temperature, and digestion of food. If a subject is removed from the influence of these factors, the metabolism corresponds to the energy exchange for the minimal functional activity of the body. The term *basal metabolism* has been applied to the energy changes of the body under these conditions. It is usually determined twelve to fourteen hours after the last meal with the subject at rest and in a comfortable environmental temperature. Krogh has suggested the term *standard metabolism* for the heat production under these conditions since the metabolism can be lowered from the "basal" level by sleep or drugs. Benedict uses the term "postabsorptive" for the same reasons. The term *basal metabolism,* however, has taken a definite meaning and is commonly used in this country.

Surface Area.—Basal metabolism is reported in terms of Calories per square meter of body surface. Rubner established this empirical relationship by measuring the metabolism of dogs of various sizes and of other mammals varying in weight from 18 grams to 128 kilograms. His results are given in Table XLV.

TABLE XLV

RELATIONSHIP BETWEEN HEAT PRODUCTION AND BODY SURFACE (From Rubner[88, 89])

DOGS		VARIOUS MAMMALS		
WEIGHT IN KILOGRAMS	CAL. PER SQ. METER BODY SURFACE PER 24 HR.	ANIMAL	WEIGHT IN KILOGRAMS	CAL. PER SQ. METER BODY SURFACE PER 24 HR.
31.20	1036	Hog	128.00	1074
24.00	1112	Man	64.00	1042
19.80	1207	Dog	15.00	1039
18.20	1097	Guinea pig	0.50	1246
9.61	1183	Mouse	0.018	1185
6.50	1153			
3.19	1212			
Averages	1142			1145

It was later shown that Rubner's figures for the number of Calories per square meter of body surface were too high as compared to modern standards. The same relationship, however, holds for the revised values (Table XLVI).

TABLE XLVI

RELATIONSHIP BETWEEN HEAT PRODUCTION AND BODY SURFACE IN MEN (Rubner's Analysis of Material Taken From Benedict's Determinations[84])

NO. OF INDIVIDUALS	AVERAGE WEIGHT	VARIATION IN WEIGHTS	CALORIES PER SQ. METER BODY SURFACE
	kg.	kg.	per 24 hours
6	48.7	40-50	922
41	53.4	50-60	914
164	64.5	60-70	927
24	74.7	70-80	924
8	83.7	80-90	924
			Average 922

Is there any explanation for this relationship? In physical systems, the rate of cooling is dependent upon the area of the body and upon the difference in

temperature between the body and the surrounding atmosphere. This law does not apply to the body of a warm-blooded animal since the rate of heat loss is not changed in proportion to the temperature of the surrounding atmosphere. If it were, there would be no need for any heat production when the external temperature equals body temperature. Further, Harris and Benedict showed that a dog kept in their laboratory for several months had a decrease in metabolism of 19 per cent without any change in body surface. Benedict obtained similar results in studies on a man during starvation. In infants, the total metabolism is more nearly proportional to the body weight than to surface area. Obviously, it is not clear why there should be even a rough correlation between metabolism and body surface. In this connection it is of interest to note that vital capacity, cardiac output, and cross section of the aorta and trachea are also related to the surface area of the body.

Part of the difficulty in accepting the relationship between metabolism and surface area as a fact of fundamental significance arises from the inaccuracy of the measurement of the latter. In 1879, Meeh marked out in geometric designs the bodies of six adults and ten children. From these measurements, he derived the formula $S = KW^{\frac{2}{3}}$, where K is a constant for a given species. Rubner used this formula in his calculations of the surface areas of animals. Benedict[49, 50] has discussed critically the use of this formula. He points out that in the case of the rabbit 13 per cent of its body weight may be intestinal contents. It would introduce a large error to calculate surface area of a rabbit on a weight basis when so much of the weight is made up of metabolically inert material. The same problem arises in the case of ruminants where a large portion of the total body weight may be derived from intestinal contents. The exponent 0.666 has also been revised by various writers, some using a value as low as 0.53, others one as high as 0.80.

The most variable factor, however, has been the so-called constant K. Benedict[49] has evaluated this constant for a large number of laboratory animals. He describes the difficulties in measuring the surface areas of animals of simple geometric design, such as the snake. The actual measurement of the area of the skin after removal from a snake always gives a greater value than the calculated one in spite of all precautions to avoid stretching. Mitchell has shown in the case of the rat that the surface area depends on the position of the animal. Also, the values of K used by Rubner[64] varied from 4.62 for the frog to 18.6 for the snake. From a study of the more recent literature, and from his own determinations, Benedict has shown that the average value of K is close to 10 for all species.

The same difficulty arose when the Meeh formula was applied to man. DuBois and DuBois[76, 77] determined the surface area of a small group of individuals by measuring paper casts of their bodies. They derived a formula which was based on height and weight:

$$\text{S.A.} = W^{0.425} \times H^{0.725} \times 71.84$$

where S.A. is surface area in square centimeters, W is weight in kilograms, and H height in centimeters. This formula has been used to construct graphs from which the surface area of any individual may be determined when the height and weight are known (Fig. 283). Although they derived this general formula

from a study of a small group of individuals, other observers have determined the surface area of man and have found that this mathematical relationship does hold for a large number of individuals.

There are, therefore, two variables in the consideration of metabolism in man and animals. The metabolism itself can be determined very accurately by a large number of methods, while the surface area is more difficult to measure. The variability in surface area measurements no doubt accounts for the fact that the basal metabolism of some individuals differs widely from the accepted standards. Boothby and Sandiford analyzed the results of determinations of basal metabolic rates of 8,614 patients and found that 77 per cent of this group fell within ± 10 per cent of the normal standards and 90 per cent fell within ± 15. Thus, 10 per cent of this group fell outside the wider limits. It is customary, however, to consider ± 15 per cent the normal variation from the accepted standards of basal metabolism. Since these standards were derived from tests on patients, it is not surprising that individuals accustomed to metabolic tests should give results that are below these values.

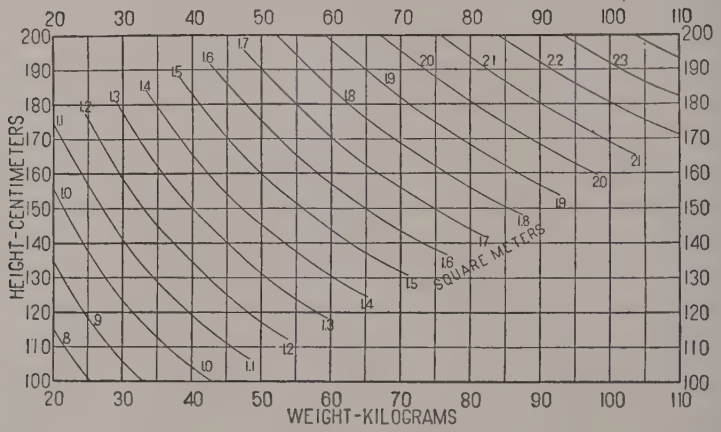

Fig. 283.—Chart for determining surface area of man in square meters from weight in kilograms (Wt.) and height in centimeters (Ht.) according to the formula: Area (Sq. Cm.) $= Wt.^{0.425} \times HT.^{0.725} \times 71.84$. (From DuBois and DuBois: Arch. Int. Med. 17: 863, 1916.)

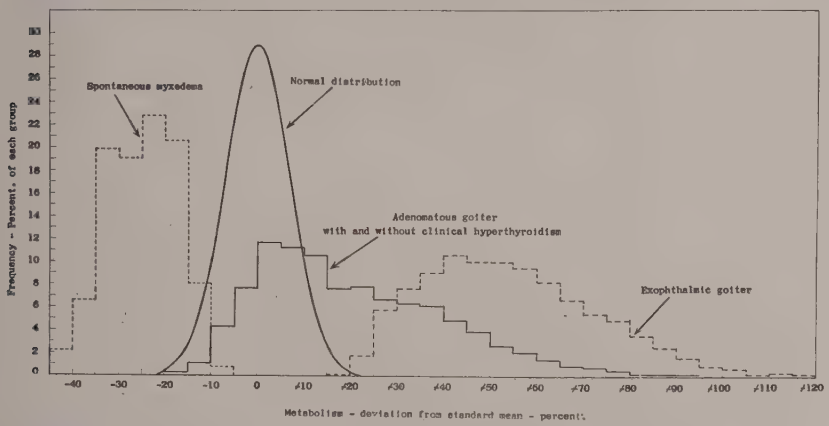
Although "heat per square meter of surface area" does not represent a thermal law, it will be used for practical purposes until a better standard is obtained. Benedict[49] suggests that the emphasis should be shifted from a comparison of metabolism with heat loss to a consideration of the relationship of metabolism to heat production. This is the work of the future. He believes that the relationship between heat production and surface area is wholly fortuitous.

The various factors which affect basal metabolism were listed at the beginning of this chapter. Carpenter[52] has reviewed the magnitude of the changes due to several of these as follows:

Minor Muscular Movements.—The subject must remain perfectly quiet during the determination. Benedict and Benedict have determined the effect

of slight arm and leg movements, such as raising the hand to the forehead every few seconds, or crossing and uncrossing the legs every twenty seconds. In one individual the arm movements changed the metabolism from a basal value of 200 ml. oxygen to 210 ml. per minute, while the leg movements raised it to 222 ml. Therefore, movements such as these should be avoided. The subject should be placed in a comfortable position so that there will be no desire to change position during the determination. The usual motions of rising, dressing, and walking to the laboratory do not affect the basal values provided that the subject rests for thirty minutes before the test. On the other hand, after strenuous muscular exercise the metabolic rate may not return to the basal level for several hours (see page 842).

Temperature.—The subject must be in a room at a comfortable environmental temperature. In the course of his studies of cardiac output, Grollman[80] measured the metabolism of a subject exposed to temperatures ranging from



Spontaneous myxedema
Normal distribution
Adenomatous goiter
with and without clinical hyperthyroidism
Exophthalmic goiter
Frequency - Percent. of each group
Metabolism - deviation from standard mean - percent.
-40 -30 -20 -10 0 +10 +20 +30 +40 +50 +60 +70 +80 +90 +100 +110 +120

Fig. 284.—Basal metabolism in three thyroid diseases compared with group of normal individuals. Percentage frequency distribution for each group. (From Boothby, Berkson, Plummer: Ann. Int. Med. **11**: 1014, 1937.)

0° to 45° C. The metabolism at 0° was 330 ml. of oxygen; it decreased to 240 ml. at 30°, and then rose with increasing temperatures, reaching 260 ml. at 40°. The rise at the lower temperature is attributable to shivering and increased muscular tone. The gradual decline from 20° to 30° is due to greater muscular relaxation. The increase from 30° to 45° may be due to an increased reaction velocity of the chemical processes in the cells. It may also result, in part at least, from the increased activity of the sweating, respiratory and cardiac mechanisms. DuBois has calculated that the metabolism increases about 13 per cent for each degree rise of body temperature. It is, therefore, very important in metabolic experiments to record the temperature of the subject and of the room.

Age.—The standards given in Table XL are divided into various age groups. Very few persons, however, have been followed over long periods of time. Carpenter gives data on two individuals whose metabolism was followed over a period of twenty-four years. In one person, the metabolism fell from

27.8 Calories per kilogram per day to 23.5 Calories, while in the other subject, the change was less, from 22.5 to 20.6 Calories per kilogram per day. The metabolism of many more persons should be followed over long periods of time in order to obtain sufficient data on the effect of age.

Racial Variations.—Compared with American standards, natives in Yucatan have a higher metabolism (+8.4 per cent) while a group of female students at Madras, India, were found to have a much lower one (–17.4 per cent). A group of Chinese women living in America had an average metabolism 10.4 per cent below American standards. These few examples illustrate that there may be significant deviations in the metabolism according to race.

The effect of ingestion of food will be discussed in the separate chapters on proteins, fats, and carbohydrates. It is impractical to discuss in detail the many minor factors which may affect basal metabolism. Previous diet, novelty of procedure, climate, degree of muscular development, over- or under-nutrition may influence the metabolism slightly. For practical purposes, it is customary to take the lowest value obtained in a series of determinations; the majority of the factors mentioned above raise the metabolism.

Application of Basal Metabolic Studies to Clinical Conditions.—Since the introduction of standard methods of determination of basal metabolism and of adequate standards for comparison, many studies have been made on patients. The most practical result of this work has been the use of basal metabolic studies in aiding the diagnosis of doubtful cases of hypo- or hyperthyroidism. Boothby, Berkson and Plummer[72] have analyzed the percentage frequency distribution for thyroid diseases (Fig. 284). It may be seen from the figure that patients suffering from myxedema and exophthalmic goiter fall, with few exceptions, outside the normal group, but those with goiter are distributed between the normal and exophthalmic groups. In addition to an aid to diagnosis, basal metabolic tests can be used to obtain evidence concerning the value of medication in thyroid diseases and to determine the time for operation in the hyperthyroid cases.

Basal metabolic tests are also useful in cases of obesity and diabetes, for they aid the physician in understanding the nutritive condition of the patient and thus help him to prescribe an adequate diet. These tests have also been used as a postoperative procedure after the removal of the thyroid gland in cardiac cases. Since there is a relationship between metabolic rate and cardiac work, the thyroid gland has been removed in order to decrease the work on the heart. The basal metabolic test gives exact information on the change in metabolism and the decrease in cardiac work following such an operation.

CHAPTER L

THE METABOLISM OF CARBOHYDRATES

Carbohydrate is the chief fuel of the body, for more than two-thirds of the required energy is supplied by its oxidation. In addition it enters into the composition of many substances, such as nucleic acids and cerebrosides, which form part of the basic tissue framework. The regulation of its storage and metabolism is more clearly understood than is that of protein or of fat. Knowledge of this control has been gained mainly from the study of diabetes as it occurs in man or as it is experimentally produced in animals. In this disease the abnormal carbohydrate content of the blood and urine may be analyzed by accurate chemical determination and controlled by insulin injections.

The Absorption of Carbohydrates.—The carbohydrates of the food are of three general types: polysaccharides which may be hydrolyzed into monosaccharides by the action of the digestive enzymes; polysaccharides which resist hydrolysis; and monosaccharides. The nonhydrolyzable polysaccharides are excreted in the feces while the other polysaccharides are broken down into their constituent monosaccharides and are absorbed along with the monosaccharides occurring in the food. Cori[119] has demonstrated a differential rate of absorption for the hexoses. He found that galactose is absorbed faster than glucose which, in turn, is taken up by the blood at a faster rate than fructose or mannose. The rate of absorption depends on the chemical structure of the sugar and not on the absolute amount of sugar present in the intestinal tract. In the normal animal the latter factor affects only the duration of absorption. For a more detailed discussion of this subject see Chapter LXVIII.

Blood Sugar.—Following the ingestion of carbohydrate, there is an increase in the blood sugar. The normal level varies between 70 and 120 mg. per 100 ml. of blood.

The amount of sugar in the blood is determined by measuring the reducing power of a sample after removing the proteins. Numerous micromethods have been developed for this purpose. Since these methods determine the total reducing substances present in the sample of blood, none is specific for glucose. Glucose does, however, make up the greater part of the total reducing material; the remainder is composed of such substances as creatinine, thioneine and glutathione. The method that gives the closest approximation to the true glucose concentration involves a combination of reduction and fermentation. In this procedure the reducing power of the solution is determined before and after yeast fermentation. Assuming that the yeast reacts only with glucose, the difference between these two values gives the true glucose content. For most clinical purposes, however, the reduction alone yields results of sufficient accuracy. Different sugars have various powers of reduction. Hawkins[143] has shown that if a given weight of glucose be taken as a standard and given a reducing value of 1.00; equal weights of the other sugars have the following reducing powers: mannose 1.02; galactose 0.79; fructose 0.99; arabinose 0.95; xylose 1.02; maltose 0.73; and lactose 0.73. These ratios as well as the normal basal values of the blood sugar vary slightly with the method used. Van Slyke and Hawkins[192] have compared the values obtained for the blood sugar level when different methods are used. It is interesting to note the different results obtained from the same blood with the different methods (Fig. 285).

After removal of blood from the body its sugar content may decrease even when it is kept under sterile conditions. Evans[128] has shown that the disappearance of sugar under these conditions is accounted for by the appearance of lactic acid. It is necessary, therefore, to analyze blood immediately after withdrawal from the body or to inhibit the glycolysis by the addition of fluoride.

Glucose Tolerance Test.—The blood sugar changes that occur after the ingestion of glucose have been incorporated in a test for the capacity of the body to absorb and to utilize carbohydrate. The main essentials of this test consist in giving 50 to 100 grams of glucose by mouth and then determining the concentration of sugar in the capillary blood at fifteen-minute intervals

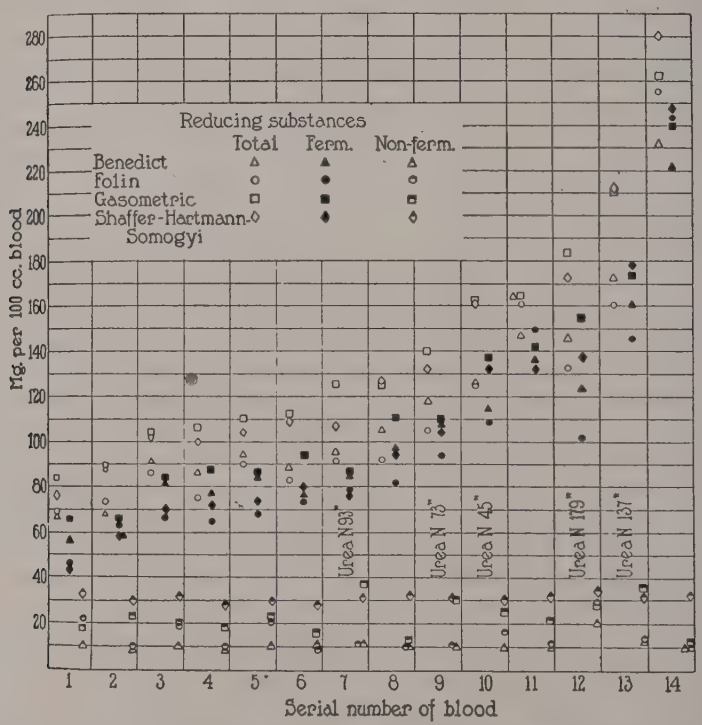


Fig. 285.—Values of normal blood sugar analyses obtained by different methods. (From Van Slyke and Hawkins: J. Biol. Chem. 83: 51, 1929.)

for several hours. Gilbert, Schneider and Boek[147] determined the variation in the course of the sugar curves in a group of individuals each of whom received in 400 ml. of water 1.75 grams of glucose per kilogram of body weight. They found that the maximum rise is reached in from fifteen to forty-nine minutes and that the maximal concentration varies from 136 to 206 mg. per 100 ml. of blood. The return to normal was found to take place in two and a half hours. In some individuals a secondary rise occurred. The rise in blood sugar is not directly proportional to the amount of glucose taken; large doses merely prolong the hyperglycemia and require more determinations in order to

obtain the complete curve. Peters and Van Slyke[167] recommend 1 gram of glucose per kilogram of body weight as the optimal amount to be given in carrying out a tolerance test.

In the individual suffering from diabetes mellitus an entirely different curve is obtained after ingestion of glucose. The maximal rise is greater, reaching values as high as 300 mg. per 100 ml. of blood, and the return to the base line is delayed (Fig. 286). The maximal rise, in contrast to the response of a normal subject, is proportional to the amount of sugar ingested. This test, therefore, is of special value in the diagnosis of diabetes. A normal response in an individual is fairly good evidence that the subject is not suffering from this disorder. An abnormal response, although it may be the result of other pathological conditions, must be looked upon with suspicion even if the level of the postabsorptive blood sugar is within normal limits. The earliest sign of diabetes is an unusual degree and duration of the postprandial hyperglycemia. In the diagnosis of diabetes the duration is of more importance than the degree of the hyperglycemia.

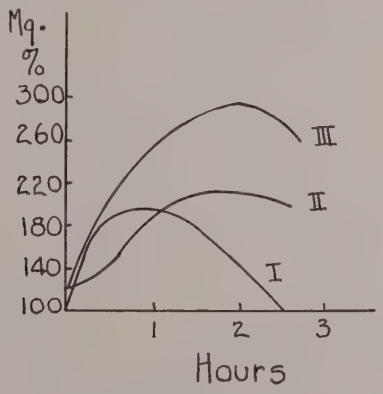

Fig. 286.—Capillary blood sugar curves (compiled from various sources). I, maximal normal rise after ingestion of 1 gram of glucose per kilogram of body weight; II and III, rises in a diabetic subject after ingestion of 35 and 58 grams of glucose, respectively.

Numerous modifications of this test have been suggested. Traugott,[191] Exton and Rose[129] and others have proposed a two-dose test, in which the second ingestion of glucose is given about one hour after the first. These tests are based on the fact that the more glucose that is given to a normal individual, the more the normal individual will use, whereas this is not the case in the diabetic. The authors of these tests claim that they are more specific for the diagnosis of the diabetic condition than the usual one-ingestion test.

Fate of Ingested Carbohydrate.—The glucose tolerance tests demonstrate that in a normal person the blood sugar returns to a normal value within a period of from two to two and a half hours after the ingestion of 100 grams of glucose. The processes which may be involved in the disappearance of the sugar from the blood are the following:

1. *Removal From Blood Stream by Diffusion.*—Some of the glucose passes directly into the tissues following the increased concentration in the blood.

Folin, Trimble, and Newman[132] observed that the percentage of sugar in the skin varies with the amount in the blood. No chemical change in the sugar molecule takes place in this process and the concentration in the tissues follows the level in the blood. Cori, Closs and Cori[122] have shown that the fermentable sugar in skeletal muscles of rats amounts to 10 to 12 mg. per cent at plasma sugar levels of 80 to 120 mg. per cent. At the same blood plasma level heart muscle has a higher concentration of glucose than skeletal muscle. Cannon[117] has called the process of diffusion of sugar into the tissues "storage by inundation."

2. *Conversion of Glucose to Glycogen.*—In contrast to the simple overflow of carbohydrate into the tissues there is another form of storage in which the glucose is changed chemically to glycogen. Cannon[117] describes this process as "storage by segregation." In contrast to the large amounts of glycogen found in the liver, muscles, and other tissues, the amount of carbohydrate present in the body as glucose is very small. Cori[120] has determined the rate of glycogen formation in the livers of rats following the ingestion of various sugars. Fructose and glucose form glycogen at equal rates, whereas galactose does not form glycogen readily. Glycogen formation reaches a maximum after four hours of absorption of fructose and glucose. In Cori's experiments, the liver was able to store only 17 per cent of the absorbed glucose and 39 per cent of the fructose.

The liver is essential not only for storage of sugars but also for the transformations which sugars or sugar-producing substances undergo in order that they may be utilized by the body. Mann[162] found that glucose or fructose can be used for the maintenance of the blood sugar level in an animal from which the liver has been removed. Other substances, such as glycine and lactic acid, cannot be used by these animals and, therefore, it may be concluded that they must undergo a preliminary transformation in the liver before they can be used in the animal body. The glucose circulating in the blood may be built into glycogen in muscles and other tissues as well as in the liver. Cori and Cori[120] observed that of ingested glucose 18 per cent is deposited as liver glycogen while 25 per cent is found as glycogen in other tissues of the body.

3. *Oxidation of Glucose.*—In this same work, Cori and Cori determined the amount of glucose oxidized by rats during the four hours following glucose ingestion. Nearly all the sugar was accounted for by the two mechanisms: glycogen formation and carbohydrate oxidation. In contrast to our knowledge of the intermediate steps in the breakdown of glycogen very little is known about the direct utilization of glucose by tissues. The increased oxidation of carbohydrate following absorption of glucose may be due to the combustion of the glycogen formed from the glucose and not to the oxidation of glucose itself. Evidence has been presented that the brain and heart are able to use glucose directly. Ashford and Holmes[102] have shown that glucose may be converted to lactic acid by chopped brain tissue. Gaddie and Stewart[133] have investigated the action of glucose and mannose on the fatigued heart. These substances serve to reduce fatigue developed under anaerobic conditions. Since the formation of glycogen from glucose requires energy which may be obtained from oxidative processes, these experiments suggest that the glucose may be used directly for the production of energy. Although glucose may be oxidized to a limited extent, the conversion of glucose to glycogen and the oxidation of the glycogen is of greater importance in the carbohydrate cycle.

4. *Removal by Kidneys.*—There is a limit to the amount of carbohydrate that an animal is able to absorb without the occurrence of sugar in the urine. The total amount which may be tolerated without glycosuria is called the *assimilation limit.* This varies with the type of sugar ingested and with the rate at which the tissues are able to take sugar from the blood. In order to determine the latter factor, Woodyatt, Sansum and Wilder[198] developed a method for continuous injection of sugar solutions into man and animals. They found that a man weighing 70 kilograms was able to absorb 63 grams of glucose per hour by vein without exhibiting glycosuria. The average normal tolerances for various sugars are given in Table XLVII.

TABLE XLVII

NORMAL TOLERANCES FOR VARIOUS SUGARS INJECTED INTO A VEIN (WOODYATT, SANSUM AND WILDER[198])

SUGAR	TOLERANCE (GRAMS PER KILOGRAM BODY WEIGHT PER HOUR)
Glucose	0.85
Fructose	0.15
Galactose	0.10
Lactose	0.00

The limit of assimilation of glucose following ingestion of sugar by mouth is much greater than the values given above for injected sugars. Taylor and Hulton[190] fed varying amounts of sugar to a group of subjects and found that some individuals were able to tolerate as much as 400 grams of glucose without showing glycosuria. The reason that man is able to withstand such large amounts of ingested sugar is that the maximal rate of absorption from the intestine is less than 1 gram per kilogram of body weight per hour. This is a limit which lies just within the tolerance found by Woodyatt and his associates for the slow intravenous injection of glucose. These findings explain why the tolerance of man to the carbohydrate in his food is practically without limit. There are some individuals, however, who do develop *alimentary glycosuria.* In these, the glycosuria may not develop until after the peak of the blood sugar curve has been reached, and then the kidneys may continue to pass glucose even when the blood sugar has fallen to the normal level. Therefore, there are two thresholds for glucose, one for the ascending blood sugar and one for the descending, the latter threshold being lower than the former.

5. *Conversion of Carbohydrate to Fat.*—It is assumed that carbohydrate may be converted into fat. The only experimental evidence for this conversion

TABLE XLVIII

THE MAXIMUM CONVERSION OF CARBOHYDRATE TO FAT (FROM RAPPORT[169])

OBSERVER	ANIMAL	FAT DEPOSITED IN 24 HOURS	
		AMOUNT (GRAMS)	PER CENT OF BODY FAT
Munk (1885)	Dog	37	0.1
Rubner (1886)	Dog	20	0.3
Lehmann and Voit (1901)	Goose	18	0.4
Bleibtreu (1901)	Goose	104	2.2
Meissl (1886)	Pig	364	0.2
Rapport, Weiss and Csonka (1924)	Pig	82	0.3
Baumgardt and Steuber (1920)	Man	148	0.25

has been obtained during the feeding of excessive amounts of sugar (Table XLVIII). Whether this conversion occurs during the ingestion of normal amounts of carbohydrate has not been determined experimentally nor has the exact chemical nature of the conversion been demonstrated. Leathes and Raper[152] have suggested that aldehydes condense to form long chain unsaturated compounds which in turn are oxidized to fatty acids:

$$4CH_3CHO \rightarrow CH_3(CH)_6CHO \rightarrow CH_3(CH_2)_6COOH$$

Smedley and Lubrzynska[182] have postulated another pathway, one in which pyruvic acid combines with an aldehyde to form a keto-acid; the latter is then oxidized to the corresponding fatty acid.

Noncarbohydrate Sources.—Carbohydrates may be formed from other foodstuffs. Experimental evidence for the change of protein into carbohydrate has been obtained by several methods. Williams, Riche and Lusk[195] studied the output of nitrogen and carbon following the feeding of 1200 grams of meat to a dog. They found that the respiratory carbon dioxide was less than the theoretical amount calculated on the basis of complete protein oxidation. The remainder of the carbon evidently had been stored either in the form of fat or carbohydrate or both. More direct evidence of the transformation of protein to carbohydrate has been obtained in the diabetic animal. Reilly, Nolan and Lusk[170] fed a phlorhizinized dog 500 grams of meat and found that the urinary output of glucose and nitrogen doubled. From these results, they calculated that 58.7 per cent of meat protein may be converted into sugar. Comparable results have been obtained in pancreatectomized animals and in persons suffering from diabetes. Not all the amino acids give rise to extra sugar in the diabetic animal. Dakin[124] found that glycine, alanine, serine, cysteine, proline, ornithine, and arginine are converted into glucose while valine, leucine, isoleucine, lysine, histidine, phenylalanine, and tryptophan give little or no sugar. Such experiments may be criticized on the ground that since they were carried out in the diabetic animal the results may not apply to the normal. Evidence, however, has been obtained by feeding normal animals protein and amino acids after most of the supply of carbohydrate had been removed by starvation, muscular exercise, exposure to cold, or by administration of strychnine. After diminishing the glycogen stores in rats Wilson and Lewis[196] found that alanine, casein, or gelatin may increase the amount of glycogen in the bodies of these animals. More recently, Butts, Dunn and Hallman[116] have shown that dl-phenylalanine causes a deposition of glycogen when fed to fasting rats.

Another possible source of carbohydrate is fat. The evidence for this transformation, however, is not as definite as that for the conversion of protein into carbohydrate. Soskin[183] fed fat and lecithin to diabetic dogs. In three out of fifteen experiments he observed an increase of sugar in the urine. In numerous experiments fat has been fed animals after a period of starvation. The small changes observed in the sugar content of these animals may be accounted for by the transfer of the glycerol in the neutral fat to glycogen. Gemmill and Holmes[135] found low respiratory quotients (0.41-0.72) and definite increments in the carbohydrate content of livers taken from rats on a butter diet. Weil[194] has demonstrated that acetoacetic acid is converted into carbohydrate in kidney slices. Blixenkrone-Møller[108] has shown that a change of butyrate to carbohydrate can take place in the perfused liver. Although the

amount of carbohydrate coming from fat may be small, the possibility of its conversion must be considered in any metabolic process.

Many non-nitrogenous substances, such as glycollic aldehyde ($CH_2OH.CHO$), lactic acid ($CH_3CHOHCOOH$), and glycerol ($CH_2OHCHOHCH_2OH$) are convertible to glucose.

The Specific Dynamic Action of Glucose.—Following the ingestion of sugar there is an increase in metabolism. The rise in metabolism is related to the existing glycogen stores in the body. Dann and Chambers[125] found that glucose fed a fasting animal produces a greater rise in metabolism than when the same amount of glucose is fed an animal on a normal diet. This change in the metabolism may take place in the muscles, for removal of the liver does not abolish the rise; it may be associated with the production of glycogen from glucose.

The Fate of Glycogen.—If liver tissue containing glycogen is removed from an animal, the glycogen content decreases while the concentration of glucose increases. The enzyme responsible for the breakdown of glycogen into glucose is called glycogenase. Macleod[157] studied the distribution of this enzyme in various tissues by determining the extent of glycogenolysis. His results are given in Table XLIX.

TABLE XLIX

DISTRIBUTION OF GLYCOGENASE (MACLEOD[157])

ORGAN	PER CENT GLYCOGENOLYSIS IN 4 HOURS
Pancreas	100.0
Liver	88.6
Serum	83.3
Kidney	48.9
Muscle	0.0

It is interesting to note that the pancreas contains the greatest amount of this enzyme. There must be some mechanism or arrangement in the tissues whereby this enzyme is separated from the glycogen; if this were not the case the organs would not be able to store glycogen.

Although withdrawal of food reduces the glycogen content, small amounts may be found even after long periods of starvation. It has long been recognized that vigorous exercise (Külz[150]) and exposure to cold (Külz[151]) are effective means of depleting the store of liver glycogen. The glucose formed under these conditions is transported to the tissues where it is used as fuel. The various factors which cause considerable changes in liver glycogen do not affect muscle glycogen to the same degree. For example, starvation of two or three days' duration may cause nearly all the liver glycogen to disappear without producing any marked changes in muscle glycogen. Severe exercise, however, will reduce muscle glycogen. The chief intermediate product of glycogen breakdown in the muscles is lactic acid, not glucose. The breakdown of glycogen to lactic acid is discussed in the chapter on the Chemistry of Muscular Contraction (Chapter LII).

CHAPTER LI

THE CONTROL OF CARBOHYDRATE METABOLISM

The level at which the concentration of the sugar in the blood is maintained represents a balance of the numerous factors discussed in the previous chapter. The two main elements are the utilization of glucose by the tissues and its liberation from the liver. Since the need for sugar by the tissues is a variable one, mechanisms exist whereby the production of sugar in the liver may meet the demand for glucose.

NERVOUS AND NEUROHUMORAL CONTROL OF CARBOHYDRATE METABOLISM

Pontile Injury.—The first evidence that the blood sugar level is under the control of the central nervous system was obtained by Claude Bernard. In the course of his investigations on glycogen (1849-1877) Bernard[107] discovered that puncture (piqûre) of the floor of the fourth ventricle causes a transitory outpouring of sugar in the urine, an event which he recognized as the consequence of a rise in blood sugar. He concluded that a center in the region of the pons controls

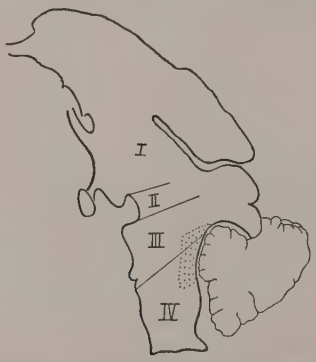

Fig. 287.—Diagram indicating the regions of the rabbit's brain through which experimental transections were made in the experiments of Donhoffer and Macleod. (From Macleod: Bull. Johns Hopkins Hosp. 54: 79, 1934.)

the blood sugar level and that the glucose mobilization in his experiments was due to irritation of this center. Since Bernard's time much work has been done on puncture glycosuria and hyperglycemia. While it is true that almost any injury of the central nervous system may cause a transitory rise in blood sugar, the somewhat more pronounced effects of a puncture of the floor of the fourth ventricle denote the presence there of some central mechanism which is in specific control of carbohydrate metabolism. Donhoffer and Macleod[127] investigated this problem by studying the effects of lesions and transections in various parts of the brain stem. For purposes of consideration they have divided the brain into four regions: Region I is rostral to the aqueduct of Sylvius; Region

II lies between I and the pons; Regions III and IV are, respectively, the pontile and distal portions of the medulla oblongata (Fig. 287). The results obtained on decerebration at these different levels are given in Table L.

TABLE L

BLOOD SUGAR AFTER TRANSECTION OF THE BRAIN STEM AT VARIOUS LEVELS (MACLEOD[99])

LEVEL OF DECEREBRATION	BLOOD SUGAR (GRAMS PER 100 ML.)						NUMBER OF EXPERIMENTS
	BEFORE	IMMEDIATELY AFTER	1 HR. AFTER	2 HR. AFTER	3 HR. AFTER	4 HR. AFTER	
I	0.102	0.127	0.139	0.145	0.155	0.174	10
II	0.123	0.125	0.125	0.139	0.130	0.160	6
III	0.110	0.155	0.195	0.241	0.286	0.291	23
IV	0.109	0.137	0.123	0.135	0.131	0.126	10

In all these experiments a steady rise in blood sugar was obtained, but it was much more pronounced when the cut was made through Region III. Similar results were obtained by Bell, Horne, and Magee[105] who decerebrated rats which had been on high carbohydrate diets.

The question arises as to the nervous pathways involved in the blood sugar changes which follow central excitation. Macleod[99] reported that the effect is abolished by cutting the splanchnic nerves. Therefore the impulses concerned either pass through the splanchnics directly to the liver or proceed over the splanchnic (preganglionic sympathetic) fibers which innervate the adrenal medulla and are capable of causing liberation of adrenine into the blood stream. It is well known that this internal secretion acts to produce a rise in blood sugar. Section of the splanchnics denervates both the liver and the adrenals and cannot therefore be used to determine which of these glands is acted upon as a result of the nervous discharge. Macleod[99] found, however, that removal of the adrenal glands without interruption of the splanchnic pathway to the liver abolishes the rise in blood sugar produced by decerebration. Previous to Macleod's work a number of investigators had found that activation of the adrenal medulla is the essential factor involved in various neurogenic hyperglycemias. Britton,[112] for example, had demonstrated the prepotency of adrenal secretion in the production of the hyperglycemia which accompanies strong emotional excitement. He showed that after removal of the medulla of both adrenal glands excitement in cats fails to raise the glycemic percentage. On the other hand, section of the sympathetic nerves to the liver scarcely modified the response.

The more recent work of Noltie[166] has confirmed and extended the findings of Macleod. This author found that midbrain or pontil decerebration evoked a marked rise in blood sugar that persisted for three to four hours. These changes did not occur if the adrenal glands were removed prior to the pontine section. From these experiments there can be no doubt that transection of the pons produces an increase in the blood sugar through liberation of adrenine from the medullas of the adrenal glands.

An influence on blood sugar may be exerted through the parasympathetic system. Following experimental exclusion of the sympatho-adrenal factor, Britton[112] obtained a lowering of the blood sugar as a result of stimulation of the peripheral end of the cut vagus nerve. Macleod[99] observed that section of the vagi or the administration of atropine abolishes the

rise which follows pontile lesions in the fasting rabbit. In rabbits with high liver glycogen the usual rise was obtained under similar experimental conditions. It is obvious that more work is needed in this field before all the pathways for the nervous control of carbohydrate metabolism can be defined with assurance.

Reflex Effects.—Additional evidence for the nervous control of carbohydrate metabolism has been secured in studies of the blood sugar changes which are produced by stimulation of afferent nerves. Griffith,[139] using rabbits, found a prompt increase in blood sugar on stimulating the central end of the cut crural or sciatic nerve. After bilateral adrenalectomy the magnitude of this reflex hyperglycemia was decreased. Stimulation of the central end of the cut vagus also increased the concentration of sugar in the blood and this change was not diminished by removal of the adrenals. Brooks[115] studied the location of the central mechanism essential for reflex hyperglycemia by testing this response in cats which had been subjected to transections of the brain stem at various levels. His results show that this reflex "center" is situated in the floor of the fourth ventricle caudal to the middle of the brachium pontis. Doubtless it is this mechanism which is thrown into action by Bernard's puncture or such transections and lesions as those practiced by Donhoffer and Macleod.

Epinephrine.—Since the adrenals play such an important part in the rise of blood sugar following reflex, emotional or direct stimulation of the central nervous system, another approach to this problem has been through a study of the changes in carbohydrate metabolism which are induced by injections of epinephrine. Experiments of this nature have been carried out, particularly by Cori and Cori.[123] Their findings are summarized in Table LI, which shows that, after injection of epinephrine, there is a decreased deposition of glycogen

TABLE LI

CARBOHYDRATE METABOLISM FOLLOWING THE SUBCUTANEOUS INJECTION OF EPINEPHRINE (0.02 MG. PER 100 GM. BODY WEIGHT IN 0.1 ML. OF FLUID) (CORI AND CORI[123])

	CHANGES PER 100 PARTS OF ABSORBED SUGAR				
	OXIDIZED	DEPOSITED AS LIVER GLYCOGEN	DEPOSITED AS GLYCOGEN IN THE REST OF THE BODY	RETAINED IN BODY FLUIDS	EXCRETED IN URINE
Controls	44	18	25	2	0
Epinephrine	39	23	15	5	6
Differences	–5	+5	–10	+3	+6

in tissues other than the liver, a decreased oxidation of sugar by the body, and an increase in the liver glycogen. In other experiments Cori and Cori determined the concentrations of glucose and lactic acid in the blood after epinephrine injections. From the results of these two types of experiments they concluded that epinephrine causes an increased mobilization of sugar from muscles and liver. The muscle glycogen forms lactic acid which is carried to the liver and is there converted into glucose which is transported to the muscles.

The total change in the blood sugar is greater than can be accounted for by the small changes in the glycogen content in the tissues (Macleod[158]). Therefore, several additional factors may be operating. There may be a decrease in utilization of sugar in the muscles or an increase in liberation of glucose from noncarbohydrate sources in the liver. Direct observation (Soskin[187])

has not demonstrated any decrease in utilization of glucose by the muscles; therefore, there must be augmented production of carbohydrate from noncarbohydrate sources in the liver. Experiments have not, however, been made to test that assumption. Regardless of the actual mechanisms involved in the production of hyperglycemia by epinephrine, the evidence is clear that the sympatho-adrenal mechanism plays a very important part in the maintenance of normal blood sugar levels.

The Hypothalamus.—In addition to the blood sugar changes observed by lesions in the pons, numerous investigators have described changes resulting from lesions or stimulation of the hypothalamus. Barris and Ingram[105] produced localized lesions in the hypothalamus in 55 cats. In 42 of these animals, a transient postoperative hyperglycemia was observed. Ten of this group showed a mild chronic hypoglycemia which was frequently intermittent. In a later review Ingram[148] described these effects as probably due to irritation resulting from the lesion. Direct stimulation of this region will also affect the blood sugar level (Magoun, Barris and Ranson[159]). Magoun, Ranson and Hetherington[160] have shown that adrenine and sympathin are liberated by continuous stimulation of the hypothalamus. The mechanism for the production of the hyperglycemia may be through the sympatho-adrenal mechanism (see page 168), since adrenine is well known to be a hyperglycemic agent (see below) and since sympathin liberated by stimulation of the cardio-accelerator nerves has been demonstrated by Bodo and Benaglia[110] to cause hyperglycemia.

THE HUMORAL CONTROL OF CARBOHYDRATE METABOLISM

The Relation of the Pancreatic Islet Tissue to Carbohydrate Metabolism

Pancreatic Diabetes.—In 1889 von Mering and Minkowski[164] observed, in dogs from which they had removed the pancreas, a persistent glycosuria accompanied by other symptoms of the disease, diabetes mellitus. The animals showed marked hunger and thirst, emaciation in spite of liberal feeding, and they died in the course of three weeks, or less. These authors reported that the extirpation must be complete to obtain this result; a small remnant of the gland sufficed to keep the animals in good health. These classical experiments demonstrated that the pancreas exerts an influence of the first importance on carbohydrate metabolism, and they led the way to the discovery of one of the most essential hormones, *insulin*.

Although von Mering and Minkowski attributed the condition of their pancreatectomized dogs to the elimination of an internal secretion of the pancreas, it was not until later that this was proved beyond any vestige of doubt. At the time of their work it was conceivable that pancreatectomy exerts its influence on carbohydrate metabolism by eliminating the *external* secretion which has its origin in the acinar tissue of the gland and is conveyed to the duodenum. In 1869 Langerhans described the pancreatic islet tissue which bears his name and which soon came to be regarded as the source of an *internal* secretion. Toward the end of the decade which followed von Mering and Minkowski's discovery a number of investigators showed that ligation of the pancreatic ducts, although followed by degeneration of the acinous tissue with scarcely any change in the islets, does not produce any of the symptoms of diabetes. Long before the preparation of an active extract capable of relieving the diabetic symptoms it was so fully established that a hormone is produced by the islet tissue that Schäfer (in 1916) gave it the name insulin. Two lines of evidence which pointed to its existence may be mentioned. (1) In 1908 Minkowski succeeded in grafting a piece of pancreas subcutaneously in a dog and found that subsequent removal of the animal's pancreas failed to induce diabetes.

(2) Later Hédon (1913) showed that transfusion of blood by anastomosis from the pancreatic vein of a normal dog to the jugular vein of a diabetic dog greatly ameliorated the symptoms of the recipient.

The course of the diabetes produced by complete pancreatectomy is more severe than that usually observed in man, and it is extremely acute from the start. Experimental diabetes very closely simulating the disease in man can be induced by excision of the greater part of the pancreas after which the animals for some months only occasionally show glycosuria, if at all. This symptom, however, becomes more and more frequent, until at last the condition typical of complete pancreatectomy supervenes. The main features of the disorder are discussed in the following paragraphs.

Glycogen.—The first change that occurs after removal of the pancreas is a disappearance of glycogen from the liver. Minkowski[165] observed that only traces of glycogen are found in the livers of pancreatectomized dogs and that feeding glucose to such animals does not restore the hepatic glycogen. These results have been confirmed by many workers. Fisher and Lackey,[130] for example, found that the liver glycogen of normal dogs fed meat for five days averaged 1.81 per cent while livers from diabetic animals on the same diet contained only 0.11 per cent glycogen; the liver glycogen of a diabetic dog fed glucose for thirteen days was only 0.045 per cent. After complete pancreatectomy the glycogen content of skeletal muscle does not change as rapidly as that of the liver. The same investigators observed that diabetic dogs on a diet of meat had a muscle glycogen content of 0.31 per cent whereas the skeletal muscles of normal control animals contained 0.58 per cent glycogen. The glycogen content of cardiac muscle actually increases, for these authors found an average value of 0.80 per cent for cardiac muscle from diabetic dogs and one of 0.50 per cent for the myocardium of normal animals. Although the values for the glycogen content of these organs vary greatly in a series of individual experiments, they do show the general trend of the changes that take place after removal of the pancreas.

The fact that the glycogen does not entirely disappear from the liver and muscle shows that these organs do not completely lose their ability to store this food material. Major and Mann[161] found that a diabetic animal could store glycogen in its liver and muscles if glucose was given, but not to the same extent as the normal animal. Barker and Sweet[104] have also shown that considerable storage occurs in the muscles if high concentrations of blood glucose are maintained. Reformation of glycogen occurs in the muscles of a diabetic animal after muscular contraction although the velocity of this process is impaired (Lukens[155]). Bodo and his associates[109] have demonstrated also that glycogen can be stored to a limited degree in the liver of a diabetic animal.

Blood Sugar.—With the decrease of glycogen in the liver and skeletal musculature, there is an increase in the blood sugar. Mann and Magath[163] have demonstrated that the liver is necessary for this hyperglycemia. After removal of its liver a diabetic dog shows hypoglycemia. The muscles may contribute indirectly to the blood sugar by the breakdown of muscle glycogen into lactic acid with the subsequent conversion of the lactic acid into glucose in the liver. Weber, Briggs and Doisy[193] have shown that diabetic muscles retain their power of forming lactic acid during muscular contraction.

Glycosuria.—Because of the rise in blood sugar in the diabetic animal there is marked glycosuria. Sugar continues to be excreted by the animal during starvation. Chambers and Coryllos[118] followed the changes in blood sugar, urinary sugar, and urinary nitrogen in successive three-hour periods after pancreatectomy. Immediately after the operation there was a rise in blood sugar and urinary nitrogen. Glucose did not appear in the urine until the blood sugar reached a level of about 0.180 per cent. They concluded that part of the early increase in the nitrogen excretion was due to tissue trauma during the operation, while the marked increase that occurred later was the result of increased protein catabolism. With the loss of glucose from the body a greater demand is made on protein metabolism for energy and for glucose.

Glucose : Nitrogen Ratio.—Many attempts have been made to relate the output of glucose in the starving diabetic animal to protein metabolism and especially to determine whether protein from the body tissues is the source of the sugar which continues to be excreted after all stores of carbohydrate have been exhausted. Theoretically it is possible to calculate, on the basis of observations made on the ability of amino acids to form sugar that 100 grams of meat protein may yield 44 grams of sugar in the animal body. Since 100 grams of protein contain, on the average, 16.65 grams of nitrogen, the ratio, $\frac{\text{grams of glucose excreted}}{\text{grams of nitrogen excreted}}$ would be constant at about 2.7 in a diabetic animal, if all the sugar were derived from protein. This ratio is called the glucose : nitrogen or G : N ratio (also the dextrose : nitrogen or D : N ratio). In experimental diabetes produced by pancreatectomy ratios approaching 2.7 are obtained only in rare cases. For example, in a series of dogs kept in good condition after removal of the pancreas, Macleod[157] found ratios which varied from 0.91 to 11.3. Doubtless the figure is influenced by the amount of glycogen stored in the liver. Closer approximations to the theoretical value of 2.7 have been obtained in diabetic animals kept on a meat diet. Minkowski[163] found ratios of from 2.63 to 3.05, averaging 2.8, under these conditions. In view of the large variations in the value of this ratio which are encountered experimentally in the starving diabetic animal, too much emphasis should not be placed on it as an index of the amount of glucose derived from protein.

Macleod critically examined the question whether the G:N ratios of diabetic animals in varying states of bodily nutrition are such as to support the widely accepted view that protein is the sole source of glucose after all available stores of carbohydrate have been used up. As indicated above, the G:N ratio does not have the constant value which in all strictness that view demands. In fact, Macleod found that after withdrawal of insulin and food the majority of diabetic dogs have ratios which are considerably in excess of 2.7. He concluded that under these circumstances sugar is being derived from other sources than protein. His interpretation of the matter was that fat represents the chief nonprotein source of carbohydrate.

Respiratory Quotient.—With the loss of carbohydrate from the body there is a fall in the respiratory quotient. Ralli, Canzarelli and Rapport[168] determined this quotient in a series of diabetic dogs before and after the ingestion of meat. They found that under basal conditions the quotient averaged 0.71 and after feeding meat it rose to an average value of 0.72. They calculated that the theoretical respiratory quotient of meat protein in the diabetic animal body should be 0.73; they deducted the amount of carbon, hydrogen, and oxygen that

would be lost by conversion to sugar. Therefore the low quotients observed in the diabetic animal may signify a combustion of protein, as such, or fat or a mixture of these two substances.

Acetone Bodies.—Acetone, acetoacetic, and β-hydroxybutyric acids are found in large amounts in the blood and urine of diabetic animals. These substances are formed during the incomplete oxidation of fats and they occur in the blood and urine of otherwise normal men and animals when the supply of carbohydrate is decreased or the oxidation of carbohydrate blocked. The mechanism of their formation will be discussed in the chapter on the Metabolism of Fat.

The formation of these nonvolatile acids disturbs the acid-base balance of the blood, since a certain amount of base must be matched against these acid ions. This reduces the available base for the carrying of the bicarbonate ions and thus there is a reduction of the carbon dioxide combining power and a decrease in the pH of the blood in the diabetic.

Polyuria.—With the loss of sugar and acetone bodies in the urine, there is an increase in the amount of water lost from the body. The loss of acetoacetic acid and β-hydroxybutyric acid removes base from the body, thus causing a removal of water from the body. However, the loss of sugar itself produces a loss of water, since a glycosuria unaccompanied by ketonuria causes an increased urinary volume (Himwich and Fazekas[144]).

Insulin.—The question arises now as to the explanation of the extra glucose appearing in the blood and urine of the diabetic animal. Two general theories have been offered: either there is a lack of oxidation of carbohydrate or there is an overproduction of sugar from protein and fat. In either case it is certain that the distribution is the result of the absence or insufficiency of an internal secretion of the pancreas.

Since the demonstration by von Mering and Minkowski[164] that the pancreas is responsible for the production of diabetes in animals, many attempts have been made to obtain an active extract from this organ. The first potent preparation was made by Banting and Best.[103] It occurred to Banting that the enzymes in the acini of the pancreas might be antagonistic to the internal secretion of the gland, and that one should, therefore, remove the acini before attempting to make an extract of the islet tissue. This was done by ligating the pancreatic duct, a procedure which causes the destruction of the acini. After acinar degeneration, an active extract was prepared that produced in depancreatized diabetic dogs a sudden fall in the blood sugar and a marked decrease in the sugar content of the urine. These experiments proved conclusively that the islet tissue of the pancreas secretes a hormone, insulin, that regulates carbohydrate metabolism. Additional evidence was obtained by making extracts from the islet tissue of certain fish, Lophius, for example, in which the islet tissue forms a separate organ. Removal of this organ causes a marked rise in the blood sugar which may be brought back to the normal level by injection of extracts made from the islet tissue.

Abel and his co-workers[100] have isolated a crystalline compound from highly purified commercial preparations of insulin. Harington and Scott,[141] using a different method, have been able to obtain similar crystalline material. Scott[179] has shown that small amounts of zinc are necessary for the crystalline formation of insulin. Chemically, crystalline insulin shows the reactions of a typical protein and has been hydrolyzed to yield the following amino acids: cystine, tyrosine, glutamic acid, leucine, arginine, histidine, and lysine. The molecular weight

of the crystallized preparation averages 35,100 (Sjörgren and Svedberg[181]). Solutions of zinc insulinate are produced commercially. They give the same hypoglycemia in a normal animal (Sahyun[175]) as the amorphous type and are useful in cases showing reactions to the usual commercial preparations of insulin.

In order to standardize preparations of insulin, the Standardization Committee of the League of Nations (Gautier[134]) has defined a unit of insulin as having the specific activity contained in 0.045 mg. of the dry crystalline insulin hydrochloride. Thus 1 mg. of the crystalline material is equivalent to 22 international units. An unknown preparation may be tested against the standard by comparing its effect with the result obtained from the standard crystalline material.

Numerous attempts have been made to prolong the activity of insulin by combining the protein molecule with compounds that would decrease its rate of absorption from the tissues. The most successful of these experiments was that of Hagedorn and his associates[140] who showed that protamine in sodium phosphate buffer formed a complex with insulin. This complex had a prolonged hypoglycemic action. Scott and Fisher[180] demonstrated that a small amount of zinc added to the protamine insuline caused further prolongation of the activity. The practical importance of these findings is that patients need fewer injections of protamine zinc insulinate than of insulin, and that their blood sugar shows only minor changes during the intervals between injections.

Greeley[138] has estimated that insulin is needed at the rate of 0.0051 to 0.035 unit per kilo per hour. These are the rates at which insulin must be injected into a fasting depancreatized dog in order to keep the blood sugar at a normal constant level.

Action of Insulin in the Normal Animal.—When insulin is injected into a normal animal the blood sugar falls rapidly and may reach a point where characteristic symptoms appear. These hypoglycemic symptoms occur in rabbits when the blood sugar reaches a level around 0.045 per cent. In this animal the first symptom is a violent convulsion, during which the animal throws itself on the ground and rolls over and over. If the animal recovers from the original fit, a series of convulsions may follow until the animal dies of respiratory failure and reduced body temperature. A very quick recovery is obtained if the animal is given glucose. Other substances, such as mannose, fructose, lactic acid, and glycerol, may relieve the symptoms to a greater or less extent. In fact, such experiments may be used in determining whether or not a given substance is capable of forming glucose in the animal body. Cori[121] has determined the complete carbohydrate balance in fasted rats following injection of insulin (Table LII). These results demonstrate a decreased deposition of glycogen with an increased combustion of sugar after injection of insulin.

TABLE LII

CARBOHYDRATE BALANCE IN FASTED RATS AFTER INSULIN INJECTION (CORI[121])

	VALUES CALCULATED PER 100 GRAMS BODY WEIGHT						
	GLYCOGEN			TISSUE SUGAR	BLOOD SUGAR	NON PROTEIN R.Q.	CARBOHYDRATE OXIDIZED
	LIVER	REST OF BODY	TOTAL				
	MG.	MG.	MG.	MG.	MG. %		MG.
Fasted 24 hours	6	128	134	46	92	0.704	–
3 hours after Insulin	4	94	98	40	80	0.736	56
Differences	–2	–34	–36	–6			
Balance				–42			+56

The fact that the rise in the respiratory quotient is not accompanied by a large increase in oxygen consumption has led to the idea that insulin promotes an isocaloric shift in the metabolism. Instead of fats being consumed to supply

the basal energy, more carbohydrate is utilized under the action of insulin. Not all workers are in agreement that sugar is oxidized when insulin is injected into an animal. Bridge,[111] for example, has infused solutions of glucose with insulin into rabbits for periods of six hours. His results are given in Table LIII. These results show a shift from liver glycogen to muscle glycogen without a great loss in total carbohydrate.

TABLE LIII

RESULTS OF INFUSION OF GLUCOSE AND INSULIN INTO NORMAL RABBITS (BRIDGE[111])

INSULIN	GLUCOSE						
UNITS PER GRAM OF GLUCOSE GIVEN	INTAKE GRAMS	EXCRETED IN URINE GRAMS	RETENTION GRAMS PER KILO NET WEIGHT				
			TOTAL	LIVER GLYCOGEN	MUSCLE GLYCOGEN	BODY FLUIDS	OXIDIZED
—	22.6	1.35	10.8	3.8	2.3	2.0	2.8
1	21.8	0.80	11.2	1.9	4.0	1.2	3.9

Action of Insulin in the Diabetic Animal.—Quantitative data for the changes resulting in a diabetic man treated with insulin are given in Table LIV.

TABLE LIV

EFFECT OF INJECTION OF INSULIN INTO A DIABETIC PATIENT (LUSK[98])

TIME	R.Q.	URINE SUGAR GRAMS	BLOOD SUGAR %	CO_2 COMBINING POWER VOL. %	BLOOD ACETONE MG. IN 100 ML.
9:30	0.72	——	0.280	39.3	104
9:45	0.75	0.60	0.240	39.6	87
10:00	0.76	0.64	0.220	40.2	73
10:15	0.78	0.48	0.210	40.8	74
10:30	0.79	0.28	0.190	42.4	56
11:30	0.79	0.11	0.120	42.2	44
12:30	0.80	0.18	0.080	44.4	39

The fall in blood and urinary sugar, the rise in the R.Q. and the CO_2 combining power, and the changes in the blood acetone content on the administration of insulin are well illustrated in this table. In addition, insulin causes glycogen to be deposited in the liver and muscles of the diabetic, causes the body weight to increase, and prolongs life.

Nervous and Chemical Control of the Secretion of Insulin.—Very little is known about the mechanisms controlling insulin secretion. Britton[112] found that the blood sugar level of cats fell when the peripheral end of the cut right vagus was stimulated. This result suggests that the secretion of insulin is under nervous control. When the pancreas is transplanted to another position in the body, thus removing all nervous connections, the blood sugar remains at the normal level. While this experiment demonstrates that a nervous control is not necessary for the maintenance of the ordinary secretion of insulin, it does not by any means exclude the possibility of such a control.

It may be assumed that a rise in the blood sugar level increases the output of insulin. Such a response would explain the difference between the normal and the diabetic glucose tolerance curves. Recently Soskin and his co-workers[185] have shown that the pancreas is not essential for the production of typical glucose tolerance curves. In depancreatized animals, receiving sufficient insulin

to maintain a constant blood sugar level under basal conditions, normal glucose tolerance curves were obtained. Therefore, additional insulin is not necessary for the production of these normal curves. Evidence that blood sugar changes may affect insulin secretion by a direct action on the pancreas has been reported by Foglia and Fernandez who found that injection of hyperglycemic blood into a transplanted pancreas causes a fall in the sugar content of the systemic blood.

Mechanism of Insulin Action.—The physiological changes following the injection of insulin into normal and diabetic animals have been explained by two different theories. The first theory is that insulin promotes the storage and combustion of sugar. Therefore, in the diabetic, the ability to store and to oxidize sugar is lost and the loss of this function produces the hyperglycemia. The second theory is that insulin controls gluconeogenesis in the liver. If this control is lost, then overproduction of glucose results from the breakdown of protein and fat molecules. The evidence for the first theory is based: first, on the failure of the respiratory quotient to rise when glucose is ingested by the diabetic; second, on the recovery from the urine of most of the sugar which had been fed to the diabetic; and third, on the rise in the quotient following ingestion of sugar and the retention of the sugar when insulin is injected into the diabetic. The overproduction theory is based on the finding that the diabetic animal may oxidize sugar under some circumstances. Mann and Magath[163] showed that an animal without the pancreas or liver removes glucose from the blood stream. Diabetic animals use and oxidize carbohydrate after a period of starvation. This finding is called the Hédon phenomenon. Animals with both the pituitary and pancreas removed (Houssay animal) show positive tests for utilization of glucose. If the diabetic animal is able to use glucose, overproduction must take place to produce the high blood sugar. Young[199] has calculated from the data of several experimenters that the total amount of sugar produced by the liver in a normal fasting or diabetic dog could not come from the store of glycogen or from protein metabolism since the production was too great to be explained by the addition of these two processes. Consequently, the extra sugar must come from fat. Therefore, the overproduction theory must include the possibility of the transfer of fatty acids to glucose as well as the production of glucose from protein. The difficulty in deciding between these two theories lies in the lack of experimental proof for a large transfer of fat to carbohydrate and in the interpretation of data on the respiratory quotient.

The two theories may be combined in the following manner. The fact that storage of glycogen in muscles occurs in the diabetic, but only to a limited degree, suggests that this mechanism may be primarily affected when insulin is lacking. The lack of available glycogen in muscles may decrease secondarily the oxidation of carbohydrate. To meet this decreased storage, the body responds with overproduction of sugar in the liver, since increasing the blood glucose concentration aids in its storage and secondarily in its oxidation. When insulin is given, the rate of storage of glycogen in the muscles is accelerated, the blood sugar falls, and the need for overproduction is removed. This theory requires that insulin acts also as an inhibitor for overproduction in the liver. Normally, a high blood sugar will decrease the amount of sugar excreted by the liver, but in the diabetic, this mechanism seems to be lacking; hence an inhibitor is necessary.

Diabetes and Tissue Metabolism.—Howitt[147] has made the interesting calculation that 1 molecule of insulin may mobilize 700,000 molecules of glucose. The small amount of active material needed in this reaction points to an enzymatic process, controlled by the presence of insulin, which is inactive or only partially active in the diabetic state. Numerous attempts have been made to study diabetic tissue with modern techniques in the attempt to discover the actual site of the action of insulin.

Shorr, Richardson and Sweet[176] have determined the respiratory quotients of excised muscular tissue of diabetic dogs. They observed that the oxygen consumption of normal and diabetic excised muscle is the same whereas the R.Q. of the diabetic tissue was 0.73 in contrast to 0.94 in the normal. Shorr[177] has shown that the low R.Q. of diabetic tissue rises after several hours in the Warburg vessel. This corresponds to the Hédon phenomenon in animals. Shorr, Richardson and Sweet[176] have shown that tissue from a Houssay animal shows a normal R.Q., indicating some oxidation of carbohydrate. Krebs and Eggleton[149] have described an increase in oxygen consumption when a solution of insulin and citrate was added to pigeon's muscle. That this reaction is specific for pigeon's breast muscle was shown by Shorr and Barker[178] and Stadie, Zepp and Lukens[189] who repeated these experiments using a variety of other muscles and obtained negative results. Gemmill[136] has shown that insulin promotes glycogen storage in isolated muscle.

Other glands besides the pancreas play important roles in the maintenance of normal carbohydrate metabolism. These are the pituitary, adrenal, and thyroid glands.

The Relation of the Pituitary Gland to Carbohydrate Metabolism

Although well fed animals in which the pituitary gland has been removed show no apparent evidences of alteration in carbohydrate metabolism, there are deficiencies which may be elicited by injection of insulin or by removal of food. Only about one-tenth of the dose of insulin required to throw a normal animal into insulin convulsions is necessary to produce a similar response in an animal lacking the pituitary gland. The second factor, removal of food, soon lowers the blood sugar and throws the animal into a hypoglycemia crisis from which it may be rescued by the prompt injection of glucose. Both of these facts point to altered control of carbohydrate metabolism, and may be explained by assuming either an increased rate of utilization of blood sugar, or a decreased formation of sugar available for blood sugar, or both processes acting together. Soskin and his associates[186] have maintained that there is a decrease in the new formation of sugar from fat because an animal that is fed an adequate amount of protein is able to maintain its blood sugar without the pituitary, but a similar animal, if kept on a fat diet, is unable to do so. They conclude that the normal fasting animal derives its sugar from both fat and protein, whereas the animal without the pituitary is able to convert only protein to carbohydrate. Since the supply of protein is limited, the animal soon becomes hypoglycemic. In contrast, Russell,[174] on the basis of respiratory quotient data, has maintained that more carbohydrate is oxidized following removal of the pituitary. Her results are summarized in Table LV.

From Table LV, it may be seen that the hypophysectomized animals absorbed less glucose, had a lower blood sugar and less deposition in muscles and liver and showed a decreased utilization of oxygen. There was a slight elevation of the respiratory quotient. The fact that the total oxygen consump-

TABLE LV

CARBOHYDRATE OXIDATION AND DEPOSITION FOUR HOURS AFTER FEEDING GLUCOSE TO FASTED RATS (RUSSELL[174])

CONDITION	GLUCOSE ABSORBED MG. PER 100 GM. BODY WT.	O_2 CONSUMPTION ML. PER 100 GRAMS BODY WT. PER HOUR	R.Q.	BLOOD GLUCOSE MG. PER CENT	LIVER GLYCOGEN MG. PER 100 GM. BODY WT.	MUSCLE GLYCOGEN MG. PER CENT
Normal, unfed	—	154	0.72	72	1.2	524
Normal, fed glucose	854	147	0.86	132	123	762
Hypophysectomized, fed glucose	568	106	0.91	79	28	520

tion of the animals without the pituitary is lowered can only mean that all their metabolic processes are slowed down. Therefore, it is difficult to accept the idea that the oxidation of carbohydrate is speeded up in such animals. A shift in the respiratory quotient from 0.86 to 0.91 is not sufficient evidence on which to base the assumption that more carbohydrate is oxidized in the absence of the pituitary gland. It is therefore more logical to assume that some process, such as the new formation of sugar from protein or fat, is inhibited.

The "Houssay Animal."—The finding of Houssay that the removal of the pituitary in addition to the pancreas reduces the symptoms of diabetes has been confirmed by many workers and extended to many dissimilar species. The essential findings in such a preparation have been summarized by Russell[173] as follows:

1. Blood glucose levels are normal.
2. Glucose excretion is much less than in depancreatized animals.
3. No ketonuria is found.
4. Survival is prolonged.
5. Glucose tolerance curves may be normal.
6. Fed glucose is retained.
7. The R.Q. rises after feeding of glucose.
8. Urinary nitrogen is less than in depancreatized dogs.
9. Glycogen is found in the liver in normal amounts.
10. Diabetes returns if anterior pituitary extract is given.

These results demonstrate that there is a balance between the activity of the pituitary gland and the pancreas on carbohydrate metabolism. The removal of the insulin control allows the blood sugar to rise; the removal of the pituitary control brings about a fall in the blood sugar; but the removal of both glands causes the animal to maintain a normal level. The explanation of these results depends on the final interpretation of the activity of these hormones: whether they act through the oxidative mechanisms for using carbohydrate, through the chemical mechanisms for gluconeogenesis, or through the storage mechanisms for carbohydrate.

The "Houssay animal" is produced only by removal of the anterior lobe, not by ablation of the posterior lobe.

Diabetes From Injection of Anterior Pituitary Extracts.—Another outstanding discovery in this field has been the production of permanent diabetes

in a dog through the injection of anterior pituitary extracts. From the anterior lobe of the pituitary body Houssay and Biasotti[146] isolated a hormone which increases the blood sugar on injection. Using a similar preparation, Young[200] has produced in a dog diabetes which continues long after the cessation of the injections. Curiously enough, these dogs are able to survive for long periods without insulin.

On histological examination of the pancreas in these animals the islets of Langerhans are found to be degenerated. Probably the high blood sugar produced by the injection of the anterior pituitary extract brings about these degenerative changes. Homans[145] and Allen[101] showed that, following removal of part of the pancreas, the islet cells of the remainder of the pancreas degenerated. Recently, Woemer[197] has infused glucose solution into guinea pigs for periods as long as twenty-eight days. In some of his animals there was destruction of the beta cells in the islets, with a compensatory increase of islet tissue. No marked glycosuria developed in these animals. The results demonstrate that, if the entire pancreas is intact, the increase of islet tissue compensates for the destruction, whereas if part of the pancreas is removed, the increase is so small that destructive changes predominate and diabetes results. More recently, Lukens and Dohan[156] have shown that cats may also be made diabetic by injection of anterior pituitary extracts, provided that one-half to three-fourths of the pancreas is removed before the injections. These animals show a recovery when insulin is given for periods of nine to thirty-two days. Lukens and Dohan describe a marked hydropic degeneration of the islets of Langerhans in the untreated cats, while the insulin-treated cats had normal islets. These results show clearly the balance between pituitary extract and insulin, and suggest that insulin therapy may bring about complete recovery in the diabetic condition provided that the treatment is started early.

The Relation of the Adrenal Cortex to Carbohydrate Metabolism

Many different types of experimentation have demonstrated that the adrenal cortex plays a role in carbohydrate metabolism. Britton[114] has summarized the carbohydrate changes resulting from various types of operations in cats. His results are given in Table LVI. This type of experimentation has re-

TABLE LVI

CARBOHYDRATE CHANGES IN ADRENAL INSUFFICENCY AND OTHER CONDITIONS IN CATS (BRITTON[114])

	PER CENT CHANGE FROM NORMAL CARBOHYDRATE CONTENT		
	Serum sugar	Liver glycogen	Muscle glycogen

2. Pancreatectomized	+586	−80	−28
3. Adrenalectomized-pancreatectomized	−16	−88	+11

vealed that a cat deprived of its adrenal glands loses the ability to maintain a normal blood sugar level and to store glycogen in its muscles and liver. Long and his associates[62] have shown that the fall in these variables is dependent on the duration of starvation following adrenalectomy (Table LVII). It may be seen in this table that the differences between the carbohydrate metabolism of the normal and adrenalectomized animals become greater as the duration of the fasting progresses. Injection of active endocrine preparations from

N	48	80	0.233	0.507
A	48	30	0.070	0.358

the adrenal cortex will restore the blood sugar and liver glycogen to the normal level (Table LVIII). Muscle glycogen is restored also if adequate glucose is given to the animal.

With the rise in liver glycogen in the treated adrenalectomized animal there is a corresponding increase in urinary nitrogen, a phenomenon which demonstrates that the extra sugar is formed from protein (Long[154]). This mechanism, however, is not sufficiently active to restore muscle glycogen. In order to bring this compound back to its normal value, glucose must be ingested by the animal. It is difficult to understand why the liver in the treated fasting animal holds its newly formed glycogen and does not liberate it for utilization by the muscles. Hartman[142] and Long and Lukens[153] have shown that the typical symptoms of diabetes following removal of the pancreas do not develop if the adrenal glands are also removed. Adequate replacement therapy by injection of adrenal cortical extracts restores the diabetic syndrome (Long[154]). The explanation of this finding may be that the removal of the adrenal glands produces a condition in which proteins may not be converted into carbohydrate. Since this is one of the mechanisms for the production of the high blood sugar in diabetes, the inhibition of this mechanism lowers the blood sugar to the normal condition.

The Relation of the Thyroid Gland to Carbohydrate Metabolism

It is well known that patients suffering from thyroid disturbances show alterations in their carbohydrate metabolism. When hyperthyroidism accompanies diabetes mellitus, the severity of the symptoms of this disease increases.

Dohan and Lukens[126] have investigated the effects of the surgical removal of both the thyroid gland and the pancreas in cats. Their results are given in Table LIX.

TABLE LIX

THYROIDECTOMIZED-DEPANCREATIZED CATS (DOHAN AND LUKENS[126])

	WEIGHT KG.	GLUCOSE GM./KG./DAY	NITROGEN GM./KG./DAY	KETONES MG./KG./DAY
Depancreatized	2.66	3.21	1.31	111.0
Depancreatized Thyroidectomized[1]	2.57	2.45	1.04	56.7
Depancreatized Thyroidectomized[2]	2.98	2.70	1.06	63.8

[1]Thyroidectomy done four to thirty-four days before pancreatectomy.
[2]Thyroidectomy done at the same time as pancreatectomy.

In Table LIX, it may be observed from the results that the removal of both the thyroid and the pancreas decreases the output of glucose, nitrogen, and ketones. These effects are not surprising, for in an animal lacking both the thyroid and the pancreas, the metabolic rate is lowered and, therefore, the velocity of all processes in the body is reduced. Rudy, Blumgart and Berlin[172] have described a case of diabetes which could not be controlled by 95 units of insulin daily. Following removal of the thyroid gland, however, 44 units of insulin were adequate for complete control of the diabetic condition. Administration of thyroid extract brought back the symptoms existing before the operation.

Additional proof that the thyroid affects carbohydrate metabolism has been supplied by Soskin, Levine and Heller.[188] These authors showed that injections of thyroid extract into a hypophysectomized animal increased the blood sugar to the normal level. This level could be maintained as long as the injections continued. With this increase in blood sugar, there was a corresponding increase in the output of urinary nitrogen. Therefore, increasing the metabolic processes in general increases the breakdown of protein. This, in turn, supplies new-formed carbohydrate to maintain a normal blood sugar level. The secondary atrophy of the thyroid gland which results from removal of the pituitary gland may play a role in the disturbances in carbohydrate metabolism produced by hypophysectomy.

CHAPTER LII

THE CHEMISTRY OF MUSCULAR CONTRACTION

SKELETAL MUSCLE

When muscles contract, the energy put out in doing mechanical work, or as heat, is derived from certain chemical transformations which take place within the muscle fibers. Thus a muscle may be regarded as a machine which transforms chemical energy into work. The magnitude of the chemical changes and the amount of work done during a series of contractions may be measured, but as yet the mechanism of this conversion is unknown. Numerous levers have been devised for following accurately the time course of the tension developed during muscular contraction. There are, however, no methods sufficiently accurate and rapid to permit a study of the chemical changes which accompany and follow a single twitch. In fact it is necessary to stimulate a muscle for several seconds before any chemical conversion can be detected and in the case of some reactions the muscle must be completely fatigued before changes sufficient to permit analysis take place. A complete knowledge of the chemistry of muscular contraction would embrace a description of the chemical events underlying (a) the contraction heat, (b) the relaxation heat, (c) the delayed oxidative heat, and (d) the delayed anaerobic heat. Our present knowledge of these matters is fragmentary although certain relevant facts have come to light.

In the study of the intermediate processes occurring during and after contraction, the following procedures have been employed: (1) electrical stimulation under aerobic and anaerobic conditions; (2) application of pharmacological agents which block certain chemical reactions; (3) isolation of enzyme systems from muscle to demonstrate that certain reactions are possible; (4) addition of chemical substances to minced muscle to study the capacity of the system to convert them to other compounds; (5) grinding of muscle tissue to determine the maximal change in response to injury; and (6) application of radioactive isotopes. On the basis of the results of these diverse lines of investigation attempts have been made to describe the *sequence* of chemical events which occurs during a single contraction. In this chapter, however, the known facts concerning the chemical changes which may provide the chief sources of energy for contraction will be emphasized. Considering the present state of our knowledge, it would be premature to attempt to correlate in any detail the chemical with the thermal and mechanical aspects of contraction. The facts will stand; the sequence and relative importance of the different reactions can be firmly established only by further progress.

Respiratory Metabolism

From a practical point of view, the most important changes which take place in a muscle during a series of contractions are the *aerobic processes.* Although a muscle is able to do a small amount of work in the absence of oxygen, it must have an adequate supply to insure complete recovery. There-

fore, much more external work may be obtained under aerobic than under anerobic conditions. An example of the great differences in energy output was obtained by Hill and Kupalov.[227] A sartorius muscle in Ringer's solution in oxygen contracted more than 10,000 times before fatigue, whereas in nitrogen the muscle underwent only 2,500 twitches.

A measurement of the oxygen consumption of a muscle enables an observer to calculate the total energy needed by that muscle during work and to compare this energy to the external work. This comparison gives the efficiency of a muscle. Another relationship, the respiratory quotient, has also been used in an attempt to evaluate the type of food material consumed in muscular metabolism.

Methods for Measuring Oxygen Consumption.—It is of interest to discuss the various methods which have been devised to measure the oxygen consumption of resting and active muscles, especially as these procedures have a general application to all organs. For small muscles or sections of tissue, the Warburg apparatus is used most commonly. In this method, the volume is controlled by a change in pressure. The amount of pressure needed to restore the gas system to its original volume is determined, and, by the use of suitable constants, this pressure reading may be converted into volume units. In contrast to the manometric method, the volumetric method measures the volume change directly. These methods have been described in detail by Dixon.[209]

The chief limiting factor in the use of these methods is the thickness of the tissue, for if it is too thick, oxygen cannot diffuse into all parts of the tissue and thus the experiment becomes a partially anaerobic procedure. Hill[226] has calculated from the utilization of oxygen and the rate of diffusion of oxygen into muscular tissue that a sartorius muscle 0.5 mm. thick would be able to contract once every two seconds without going into an "oxygen debt." Later, Hill and Kupalov[227] put these calculations to an experimental test. The results of their experiments are given above.

To obtain the oxygen consumption of a muscle in the intact animal, the usual procedure is to measure the oxygen content of the blood entering and leaving the muscle as well as the rate of blood flow. The difference between the first two determinations gives the oxygen absorbed from every milliliter of blood passing through the organ. This difference multiplied by the amount of blood which flows through the organ in a given time gives the oxygen consumption in that time. Examples of such calculations from the work of Himwich and Castle[225] are given in Table LX.

TABLE LX

OXYGEN CONSUMPTION OF MUSCLE (HIMWICH AND CASTLE[225])

WEIGHT OF ANIMAL KG.	TEMP. OF MUSCLE ° C.	WEIGHT OF MUSCLE GM.	BLOOD FLOW PER HOUR PER GRAM MUSCLE ML.	O_2 USED PER 100 ML. BLOOD ML.	O_2 USED PER HOUR PER GRAM MUSCLE ML.
23.31	39.4	110	4.08	5.33	0.217
16.12	38.0	72	9.42	2.44	0.230
14.57	41.7	64	7.98	7.22	0.576

Recently, Millikan[239] has used the reduction of muscle hemoglobin as an indicator for oxygen consumption in muscle. This method has the advantages of employing an intracellular compound which occurs naturally in muscle and

of having a very small temporal lag. With suitable optical recording, the latter factor may be reduced to 0.2 sec. Quensel and Kramer[242] have also used an optical method. In theirs the degree of reduction of the venous blood which had flowed through the muscle was determined by means of a photocell. This method has a longer temporal lag than Millikan's because the blood has to pass through the capillaries into the veins before the amount of reduction is measured.

Some of the results obtained by these various methods are given in Table LXI.

TABLE LXI

OXYGEN CONSUMPTION OF RESTING AND STIMULATED MUSCLES

MUSCLE	ANIMAL	ML. O_2 PER GRAM PER HOUR		OBSERVER
		RESTING	WORKING	
Sartorius	Frog	0.017	0.275	Gemmill
Gastrocnemius	Dog	0.36	2.22	Himwich
Soleus	Cat	0.21	4.752	Millikan
Gastrocnemius	Dog	0.53	3.54	Kramer

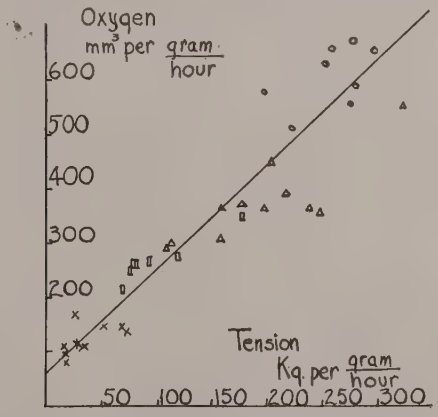

Fig. 288.—Graph showing the relationship between the tension developed and the oxygen consumed in the isolated sartorius muscle of the frog. Results of four series of experiments. (From Gemmill: Am. J. Physiol. 115: 371, 1936.)

From Table LXI, it may be seen that the oxygen consumption of a muscle is increased considerably by stimulation.

There are several factors which influence the oxygen consumption of muscle. The chief factor is the amount of work carried on by the muscle. A graphic summary of experiments correlating the tension developed in isometric contractions with the oxygen used is given in Fig. 288. It may be seen from this figure that there is a correlated increase in oxygen consumption with the increase in tension developed. A similar relationship between the amount of work performed and the oxygen consumed has been observed during moderate muscular exercise in man (see Chapter LVIII). Another factor is the initial tension; more oxygen is used at high than at low tensions under resting conditions. Since a muscle responds with a greater force of contraction at high

initial tensions than at low, it is natural to assume that the greater force of contraction would require more oxygen. This fact was observed experimentally by Fischer.[214] Therefore, the load lifted by a muscle during work affects oxygen consumption.

Efficiency of Muscular Contraction.—The relationship between the input of energy and the output gives the mechanical efficiency of any process. The efficiency of a muscular contraction has been calculated from the measurement of energy developed during isotonic contractions and the oxygen utilization. From such determinations, Fischer[214] obtained efficiencies varying from 4.1 to 13.8 per cent, with an average of 9.0 per cent. The value varies with the load, there being an optimal load for each muscle which gives maximal efficiency. The average value agrees with the efficiencies determined by Fenn[213] from heat production measurements. These determinations showed that an isolated sartorius muscle from a frog had an oxidative efficiency of 10 to 12 per cent.

Respiratory Quotient.—The respiratory quotients of resting and stimulated muscles have been determined by many observers. A summary of their results is given in Table LXII. One of the earliest studies was that of Meyerhof[236] on muscles during the recovery period. Four different sets of muscles were used in order to obtain sufficient data for the calculations of the quotient. The conditions of these experiments have been overlooked by subsequent writers who have claimed, on the basis of Meyerhof's results, that the respiratory quotient of the contracting isolated muscle is always 1.00 and that therefore the oxidation of carbohydrate supplies the sole source for the energy used in the muscular contraction. However, his results simply indicate that the quotient of the recovery period following tetanic stimulation may be unity. The more recent values (Table LXII) obtained on muscles from different animals

TABLE LXII

RESPIRATORY QUOTIENTS OF RESTING AND CONTRACTING MUSCLES

ANIMAL	R.Q.		OBSERVER
	RESTING	WORKING	
Frog	1.06	1.02	Meyerhof
Frog	0.91	0.91	Fenn
Frog	0.80	0.90	Gemmill
Dog	0.77	0.81	Himwich

demonstrate that the quotient for both the resting and contracting muscle is less than unity when the muscle is under aerobic conditions. This fact, taken into consideration with additional findings discussed in the next section, demonstrates that the muscle may use a mixture of food material in order to obtain aerobic energy for muscular contraction.

Mechanisms for the Utilization of Oxygen by Muscle.—The question of the methods by which a muscle uses oxygen and gives off carbon dioxide will now be discussed in terms of the oxidative enzyme systems (see Chapter XLVIII) present in the muscle and their application to the contracting muscle. Numerous types of experimentation have shown that the cytochrome-cytochrome oxidase system is present and active in muscular tissue. Muscle gives a strong indophenol oxidase reaction. Its respiration is cyanide and carbon monoxide sensitive and bands of reduced cytochrome appear under anaerobic conditions. In his original paper on cytochrome, Keilin[29] described the appearance of these

bands in the wing muscles of a moth on contraction. These bands disappeared when the moth stopped struggling. Urban and Peugnet[248] have observed the bands of reduced cytochrome appearing after contraction in the sartorius muscle of a frog. Moreover, Stannard[246] has made the interesting observation that sodium azide inhibits the oxygen consumption during tetanic stimulation but does not diminish the metabolism of resting muscle. Since azide inhibits the cytochrome-cytochrome oxidase system these experiments give additional evidence that this system carries the burden of the oxidative processes during tetanic contraction in which lactate is formed. The application of carbon monoxide as an inhibitor to muscular respiration is complicated by the fact that muscle has the property of oxidizing carbon monoxide. Nevertheless, Stannard[247] has shown that light reverses the inhibited respiration of muscle in the presence of carbon monoxide. This fact indicates that the characteristic reaction of carbon monoxide with the respiratory enzyme occurs in muscle.

Muscle is very rich in dehydrogenases; in fact, in most of the original work of Thunberg on these enzymes muscle was used as the enzyme source. Dehydrogenases of lactate, hydroxybutyrate, succinate, malate, citrate, tartrate, glutamate, and glycerophosphate have been demonstrated to be in muscular tissue. Muscle also has a rich supply of the coenzymes, DPN and flavine nucleotides.

These oxidative mechanisms work very efficiently. The reduced bands of cytochrome appear very quickly following stimulation. The reduction of muscle hemoglobin occurs 0.2 second after contractions have started (Millikan[239]). Using a very sensitive volumetric apparatus, Hill[228] has shown that the oxygen consumption of a stimulated muscle occurs mainly after the contraction is over. These facts demonstrate that during contraction, the general level of the oxidation-reduction potential in the muscle shifts towards the more reduced state and is only pulled back again by direct intervention of molecular oxygen.

Carbohydrate Metabolism

The metabolism of *carbohydrate* in muscle begins with glycogen [$(C_6H_{10}O_5)_n$] and ends with the products of the combustion of this substance. Most of the work on the chemistry of muscular contraction deals with this carbohydrate, the intermediate products of its breakdown, the oxygen used in its combustion and the final production of carbon dioxide and water.

The exact chemical nature of glycogen is not known. It is related to the higher dextrins and like them gives a brownish-red color with iodine. Unlike the dextrins it forms strongly opalescent solutions in water. Recent work has shown that muscle glycogen is composed of unbranched chains of twelve glucose units. It apparently exists in more than one form and the name "glycogen" is used more in terms of a standard method for its detection than to signify a definite chemical compound.

In the study of the metabolism of muscle glycogen numerous factors must be taken into consideration. The principal ones have been enumerated by Macleod[234] as follows: (1) species and age of the animal; (2) previous diet; (3) duration of fasting; (4) condition of the ductless glands; (5) season of the year; (6) cyclic changes; (7) the state of the animal (anesthesia, blood pressure, anoxemia, stunning); and (8) post-mortem changes. These factors are of special importance when one considers glycogen changes in mammalian muscle. Fortunately, to obtain comparable results with frog muscle it is sufficient to keep the tissue cold during the preparation and stimulation.

Using frog muscle Meyerhof[237] studied the disappearance of glycogen immediately after a period of contraction and its subsequent reappearance during

rest. On stimulating for thirty minutes at the rate of sixty a minute, he found a decrease in glycogen (reported as glucose) from 10.3 mg. per gram of muscle to 7.2 mg. In another experiment he stimulated two sets of muscles for fifteen minutes, analyzed one set for glycogen immediately after stimulation and the other set twenty-three hours later. The recovery group of muscles had 1.38 mg. more glycogen per gram than the first set. Experiments of this type give direct evidence that glycogen disappears during continued contraction and reappears in the recovery period. Cori and Cori[208] followed these changes in rat muscle with circulation intact. Their average results are given in Table LXIII. They confirm the results that Meyerhof obtained with frog muscle; namely, the disappearance of glycogen on stimulation and its partial return during oxidative recovery.

TABLE LXIII

DISAPPEARANCE OF GLYCOGEN DURING STIMULATION AND ITS RECOVERY AFTER STIMULATION (FROM CORI AND CORI[208])

Gastrocnemius muscle of fasting rats stimulated for fifteen seconds. Values are in milligrams of glucose per 100 grams of muscle. Each figure represents the average of the results of a number of experiments (number in parentheses) in which the muscle from one side was compared with that from the other side.

RESTING	STIMULATED	RECOVERY	
		10 MINUTES	20 MINUTES
549 (8)	356 (8)	—	—
—	296 (9)	350 (9)	—
—	—	295 (4)	339 (4)

With the disappearance of glycogen during stimulation, there is an augmentation in the hexosephosphate content (Cori and Cori[208]). This reaction is reversible, for during the recovery period, the hexosephosphate content decreases.

Lactate.—The lactate ($CH_3CHOHCOO^-$) of biological importance is the dextro-rotatory form of α-hydroxy propionate. Although analyzed and reported as lactic acid, very little non-ionized lactic acid exists at the pH of the body fluids; the greater part of this acid is ionized into lactate ions and hydrogen ions. Therefore in this chapter, the term *lactate* will be used in place of the more common but incorrect term "lactic acid."

Since the isolation of this substance from muscle by Berzelius in 1807, lactate has been associated with the chemical events underlying contraction. The precise conditions of its formation were not recognized, however, until Fletcher and Hopkins[218] in 1907 published their now classical paper on this subject. They found that resting frog muscle contains very little lactate (0.015 to 0.023 per cent), that mechanical injury, heat, or chloroform raises the lactate content, and that stimulation under anaerobic conditions induces a very considerable increase over the resting level (to 0.3 per cent). Finally, they demonstrated that during recovery in oxygen, the lactate is removed. Fletcher and Hopkins suggested that lactate, which formed anaerobically during contraction, may be oxidized or built back into its precursor during recovery. By comparing the oxygen consumed with the amount of lactate disappearing during aerobic recovery, Meyerhof,[238] in 1920, calculated that three to four molecules of lactate are reconverted to glycogen for every one that is oxidized. He concluded that part of the lactate or an equivalent amount of carbohydrate is burned to supply the energy for the re-formation of glycogen from lactate.

Evidence has been obtained that the lactate which appears under anaerobic conditions is derived from glycogen by a series of reactions in which oxygen is, of course, unnecessary.

It was first assumed that lactate is formed before or during the actual contraction of the muscle. Embden and his associates,[212] however, showed that part of the lactate is formed after the contraction. This observation has been confirmed by several observers, and it is now generally accepted that much of the lactate is produced after contraction and relaxation are over. Consequently, the formation of this substance is not a reaction from which energy for contraction is immediately derived.

A theoretical discussion by Hill[226] of the diffusion of oxygen and lactate through muscle tissue followed and in turn provoked new experiments. Hill calculated that a frog's sartorius muscle suspended in Ringer's solution can contract anaerobically six times a minute without appreciable accumulation of lactate. The lactate would have sufficient time to diffuse out into the solution

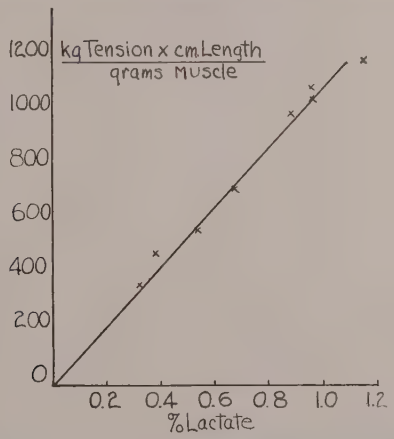

Fig. 289.—Relationship between lactate production and tension developed in isolated muscle. Abscissa, lactate per cent; ordinate, $\frac{\text{kg. tension} \times \text{cm. length.}}{\text{grams muscle}}$. (From Gemmill: Biochem. Ztschr. 246: 319, 1932.)

and never reach a "fatigue level" in the muscle. To test this calculation experimentally, Hill and Kupalov[227] mounted muscles in oxygen-free Ringer's solution and stimulated them once every eleven seconds. These muscles continued to contract for eight hours. When rapid rates of stimulation (60 a minute) were used, fatigue ensued very quickly. Gemmill[220] measured the amount of lactate developed by muscles stimulated at low frequencies in oxygen-free Ringer's solution and found a direct proportion between the lactate production and tension developed (Fig. 289). There can be no doubt that the production of lactate is associated either directly or indirectly with the development of tension under anaerobic conditions.

The question which now arises concerns the production of lactate under aerobic conditions. During short periods of tetanic stimulation, a muscle in oxygen may give rise to some lactate. This fact has been demonstrated by

Sacks, Sacks and Shaw[243] in cats' muscles (Table LXIV). It must be realized, however, that stimulation under such conditions may demand a need for oxygen greater than the oxygen supply, and thus a muscle may actually be responding anaerobically even though the arterial blood entering the muscle capillaries is fully oxygenated. From calculations of the oxygen supply in a muscle, it seems certain that a single twitch may be carried out under full aerobic conditions. Unfortunately, available chemical methods are not sufficiently sensitive to detect small changes in lactate content which may take place as a result of such a contraction. The evidence which bears on this question is very indirect and involves the question as to whether lactate is always an intermediate in carbohydrate metabolism or whether carbohydrate may be oxidized directly without going through a lactate stage. Any student interested in this complex subject should consult the article on "The Pasteur-Meyerhof Reaction" by Burk.[207]

TABLE LXIV

PHOSPHATE COMPOUNDS AND CARBOHYDRATE CHANGES IN MUSCLE DURING CONTRACTION (SACKS, SACKS AND SHAW[243])

Values expressed as mg. per cent of P and of lactate. Carbohydrate changes calculated as mg. per cent of glucose. Stimulation at rate of 1 per sec.

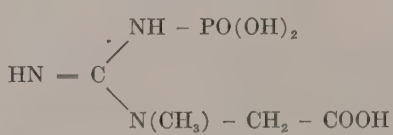
30	32	16	1.0	103	−574	20

Phosphate Metabolism.—For a long time, it was suspected that phosphate was involved in the chemical transformations which underlie muscular activity. It was not until 1927, however, that the importance of an organic compound of phosphate was clearly demonstrated. In that year Fiske and Subbarow[215] in America and Eggleton and Eggleton[210, 211] in England showed independently the existence of an unstable organic compound containing phosphate in muscle. Its chemical nature was first determined by the former pair of workers who called the compound *phosphocreatine:*



The work of these authors showed conclusively that with continuous muscular contraction phosphocreatine breaks down, and during the recovery period, is re-formed. The evidence for this is given in Table LXV-A. Nachmansohn[240] observed that even under anaerobic conditions, there is some resynthesis of phosphocreatine during recovery. The biological importance of this substance was not fully recognized until Lundsgaard[231-233] demonstrated that under a pharmacological condition, the breakdown of phosphocreatine supplied energy for muscular contraction. By poisoning muscles with monoiodoacetate, he was able to obtain the breakdown of phosphocreatine with inhibition of lactate for-

TABLE LXV-A

EFFECT OF STIMULATION AND RECOVERY ON PHOSPHOCREATINE CONTENT OF MAMMALIAN MUSCLE (SLIGHTLY MODIFIED FROM FISKE AND SUBBAROW[217])

			PHOSPHOCREATINE P	INORGANIC P

mation (Table LXV-B). He found that the phosphate from the phosphocreatine was transferred to a hexose to form hexosephosphate. He discovered also that the amount of phosphocreatine broken down was proportional to the energy liberated. These two facts led Lundsgaard to suggest that the mechanical energy developed by a muscle was related to the energy liberated from the breakdown of phosphocreatine. It is true, nevertheless, that when lactate is formed, as in an unpoisoned muscle, tension is obtainable over a longer period of time than when its formation is blocked by monoiodoacetate. In this connection, it is interesting to note that a poisoned muscle does more work when lactate is supplied externally under aerobic conditions (Mawson[235]).

TABLE LXV-B

THE BREAKDOWN OF PHOSPHOCREATINE IN NORMAL MUSCLES AND IN MUSCLES POISONED WITH MONOIODOACETIC ACID (FROM LUNDSGAARD[231])

Lactic acid in mg. per cent; phosphorus compounds in mg. per cent phosphorus.

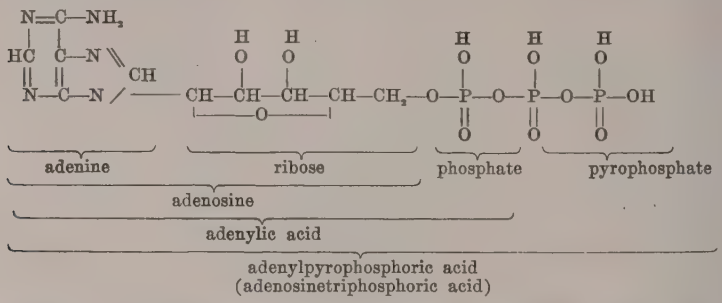
Normal	Resting	25	21	61
	Working	84	29	46
Poisoned	Resting	16	29	57
	Working	15	28	0

Another phosphate compound of importance is *adenylpyrophosphate.* As in the case of phosphocreatine, the structure and importance of this substance

have been discovered only during recent years. Lohmann[230] has determined the chemical structure of this compound. It is composed of adenine, ribose, pyrophosphate and phosphate:



Lundsgaard[233] and Sacks[243] have shown that this substance breaks down after long periods of stimulation.

Glycolysis.—In the above sections, evidence was presented that during contraction under aerobic and anerobic conditions, glycogen disappears, and that under anaerobic conditions lactate appears. Two phosphate compounds, phosphocreatine and adenylpyrophosphate, are broken down following long periods of contraction. The question now arises as to the relationships of these events. In enzymatic solutions, a definite scheme may be given for the relationships of these compounds to each other. The chief reactions in this scheme are given in Table LXVI. Inorganic phosphate is needed to form the hexosemanophosphate (Reaction 1). Adenylpyrophosphate supplies phosphate to the hexosephosphate to form the hexosediphosphate (Reaction 2). The hex-

TABLE LXVI

SCHEME OF GLYCOLYSIS

REACTION	ENZYME	COENZYME
1. Glycogen + Phosphate → Hexosemonophosphate	Phosphorylase	Adenylic acid
2. 2 Hexosemonophosphate + Adenylpyrophosphate → 2 Hexosediphosphate + Adenylic Acid	Phosphorylase	Mg++
3. Hexosediphosphate → 2 Triosephosphate	Aldolase	
4. Triosephosphate → Phosphoglycerate	Triosephosphate Dehydrogenase	DPN
5. Phosphoglycerate → Phosphopyruvate	Enolase	
6. Phosphopyruvate → Pyruvate + Phosphate	Phosphorylase	Adenylic acid
7. Pyruvate → Lactate	Lactate Dehydrogenase	DPN
8. Adenylic Acid + 2 Phosphocreatine → Adenylpyrophosphate + 2 Creatine	Phosphorylase	Mg++
9. Phosphopyruvate + Adenylic Acid → Adenylpyrophosphate + 2 Pyruvate	Phosphorylase	Mg++

osediphosphate breaks down into triosephosphate (Reaction 3) which, in turn, is oxidized to a phosphoglycerate (Reaction 4). In this reaction DPN (see page 715) is necessary. The phosphoglycerate is converted into a pyruvate (Reaction 6) and the final reaction is a conversion of pyruvate to lactate (Reaction 7). In this reaction the DPN is again involved. The association of this coenzyme in the triosephosphate dehydrogenase and lactate dehydrogenase reactions produces a coupled reaction: the first enzymatic reaction reduces the DPN, and the second oxidizes the coenzyme back to its original state. In this condition, it may once again enter into the total reaction. The role of phosphocreatine is to supply phosphate for the reconversion of adenylpyrophosphate (Reaction 8). Phosphopyruvate may act in a similar capacity (Reaction 9).

This remarkable enzymatic scheme has given rise to two schools of thought. The one applies the enzymatic scheme to the contracting muscle and claims that, under anaerobic conditions, lactate is formed from glycogen by the same steps as in the glycolytic scheme. For example, in its formation, hexosediphosphate is formed by Reaction 2, and adenylpyrophosphate is re-formed by a breakdown of phosphocreatine (Reaction 8). The phosphocreatine is re-formed by the breakdown of phosphopyruvate. This theory would explain lactate formation in muscle, and would explain why the phosphocreatine is broken down before the adenylpyrophosphate in the stimulated muscle. Another school of thought maintains that these enzymatic reactions have no direct connection with the chemical events in the muscle. In their original paper Fiske and Subbarow[217] state that phosphocreatine hydrolysis supplies base to neutralize the lactate as it is formed. Thus these two events may not be connected directly but only indirectly. The most recent evidence that the glycolytic scheme does not apply to the stimulated muscle is given by Sacks.[245] Using radioactive phosphorus in the inorganic phosphate, Sacks studied the distribution of this tracer following a short period of contraction. If the scheme of glycolysis were working in a muscle, the tracer element should have been equally distributed throughout the organic phosphate molecules as they acted as donators and acceptors in cyclic processes for the phosphate. On analysis, however, Sacks found that the adenylpyrophosphate did not take up any additional radioactive phosphorus. It was contained chiefly in the hexosemonophosphate portion. Therefore, it was concluded that adenylpyrophosphate under the conditions of these experiments does not enter into the chemical changes during contraction.

It has been recently shown by Flock, Ingle and Bollman[219] that the major changes in glycogen, phosphocreatine, adenylpyrophosphate, hexosephosphate, lactate, and inorganic phosphate occur during the first minute of muscle stimulation (Fig. 290). This may mean that these substances which have been studied so extensively are only used at the beginning of muscular exertion before a steady state is reached. When this latter condition is attained, then other substances are used. The most logical assumption to be made is that glucose from the blood stream is the chief source of energy under these conditions.

Fat Metabolism.—The discovery that an R.Q. of stimulated muscles may be less than unity (Table LXII) and that the quotient of man during exercise may also be less than 1.0 (see Chapter LVII) suggests the oxidation of non-carbohydrate material. A direct comparison of the disappearance of carbohydrate with the total oxygen consumed during a period of stimulation of

frog's muscles has shown that the oxidation of carbohydrate accounted for only a part of the total exchange during this period (Gemmill[222]). These facts demonstrate that in the frog's muscle not all of the energy for aerobic contraction may be derived from the oxidation of carbohydrate. Direct evidence that fat may be used by frog's muscle has been given by Niernierko[241] and Buchwald and Cori.[6] These observers showed that during contraction in frog's muscles taken in the summer when the carbohydrate content was low the fat content decreased. This evidence favors a definite utilization of fat by a muscle of the frog, especially when the carbohydrate supply is diminished. In order to test this question in rats, Gemmill[223] gave phlorizin to a group of these animals with the hope that their carbohydrate store might be reduced and their fat metabolism during contraction augmented. However, even after several days of phlorizin poisoning, the fat content of the stimulated muscle was not decreased. It is well known, however, that exercise diminishes the fat content of an animal's body. If this fat is not used directly, it must be used indirectly. The

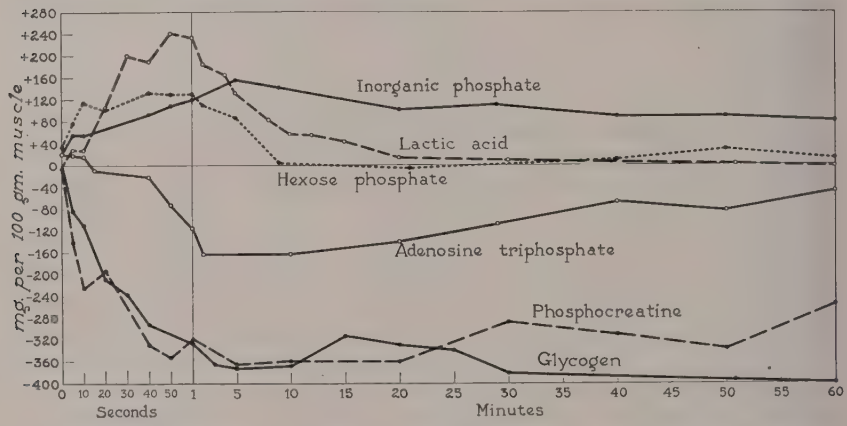


Fig. 290.—Relationship of chemical changes in muscle during continuous contraction at rate of 3 × per sec. expressed as mg. of each substance per 100 grams of muscle. (From Flock, Ingle, and Bollman: J. Biol. Chem. 129: 99, 1939.)

chief indirect method for utilization is through the conversion of fat to acetone bodies and the utilization of the acetone bodies by the contracting muscle (see Chapter LV). Therefore, in animals in which the carbohydrate supply is low or in animals with diabetes, the production of acetone bodies may be very important as a supply of metabolites for energy production by the muscle. Another fatty acid metabolite which may be used by muscle is fumarate (Harrison[224]).

Summary.—From the available evidence concerning the chemical changes occurring during muscular contraction, the following facts are evident. A contracting muscle uses and needs oxygen. The oxygen consumption is proportional to the work done, thus indicating a direct relationship between oxidation and mechanical events. The cytochrome-cytochrome oxidase system is involved in these oxidations. Carbohydrate is used during muscular work and is probably the chief fuel for muscular contraction. Under anaerobic conditions, lactate is formed in amounts proportional to the amount of work done. The interrelation of phosphocreatine, adenylpyrophosphate, and the hexosephosphates in the con-

tracting muscle is not clear although in enzymatic solutions they have a definite relationship. In the contracting muscle, these substances may act only as a reserve store of energy to be used to inaugurate muscular contraction or to be used during severe muscular exertion when the muscles are operating under anaerobic conditions. Even under these conditions the sequence of their utilization by the intact muscle has not been strictly defined. When the carbohydrate supply is low, mammalian muscle may use acetone bodies for energy production. Thus fats may be used indirectly for the production of muscular energy.

SMOOTH MUSCLE

Although the chemical changes in smooth muscle during rest and activity have not been as thoroughly studied as in skeletal muscle, certain similarities and several differences have been detected in the metabolisms of these two tissues. The oxygen consumption of resting smooth muscle is less than that of cross-striated muscle. In his review of the results on oxygen consumption for various tissues, Krebs[249] reports values for the Qo_2 ($mm.^3$ of O_2 per mg. dry weight per hour) varying from –1.3 to –3.8 for smooth muscle, while for the diaphragm, a representative cross-striated muscle, a value of –6.0 was recorded. There is very little augmentation in oxygen consumption during tonic activity although the presence of oxygen is necessary for the continued maintenance of tone (Evans[250]). On oxygenation after an anaerobic period, there is an increase in oxygen utilization, demonstrating that intermediate metabolites accumulate during that period. The chief intermediate is lactate and this substance increases in smooth muscle under anaerobic conditions, on stimulation and on mincing in alkali.

Since glycogen has been shown to disappear from smooth muscle under anaerobic conditions, it is obvious that the carbohydrate changes are very similar to those in cross-striated tissue. Data for these facts are given in Table LXVII.

TABLE LXVII

CHEMICAL CHANGES IN SMOOTH MUSCLE (EVANS[250])

CHEMICAL COMPOUND	CONDITION OF MUSCLE	BEFORE PER CENT	AFTER PER CENT	DIFFERENCE
Lactate	4.5 hours in N_2	0.016	0.092	+0.076
Glycogen	4.5 hours in N_2	0.151	0.100	–0.051
Lactate	1 hour stimulation	0.029	0.085	+0.056
Lactate	Minced in alkali	0.025	0.087	+0.062
Lactate	4.5 hours in N_2	0.016	0.079	+0.063
Glycogen	Recovery, 19 hours in O_2	0.151	0.122	–0.029

Creatinephosphate occurs in smooth muscle of vertebrates and argininephosphate in the smooth muscle of invertebrates. The phosphocreatine content of smooth muscle decreases on stimulation and increases during an aerobic recovery period (Eggleton[251]). No such recovery occurs under anaerobic conditions.

CARDIAC MUSCLE

In contrast to skeletal muscle which is normally permitted long periods of rest, the heart must beat rhythmically during the entire life of an animal. It has been calculated (Evans[254]) that during the lifetime of an average man, the heart beats 2,600 million times, pumping out at least 150,000 tons of blood from

each ventricle. Therefore, it becomes of great interest to determine the sources of energy for this organ which develops such an output of work and to compare its metabolism with that of skeletal muscle.

The fundamental difference between the metabolic activity of skeletal and cardiac muscle is that skeletal muscle has the ability to go into an oxygen debt which may be repaid during a recovery period but cardiac muscle must complete its metabolic events during each cardiac cycle. Its recovery period may not be more than 0.75 second while skeletal muscle may have hours in which to recover from violent muscular exertion. Necessarily, therefore, cardiac muscle has a strongly developed mechanism for getting oxygen into the tissues. There is no sarcolemma around the muscle fibers which might impede the diffusion of

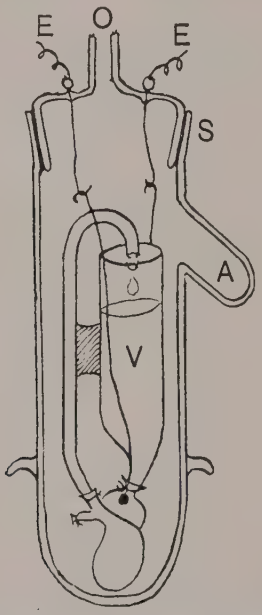

Fig. 291.—Modified vessel for Barcroft apparatus for measuring oxygen consumption of beating heart. *O*, connection to Barcroft manometer; *E*, electrodes; *A*, recess to hold sodium hydroxide for CO_2 absorption; *S*, joint to manometer. (From Clark and White: J. Physiol. **66**: 186, 1928.)

oxygen into the active tissue. There is a large capillary bed. Cobb[262] has calculated that cardiac muscle has 11,000 mm. of capillary length per c.mm. in contrast to 6,000 mm. of capillary length per c.mm. in active skeletal muscle. Cardiac muscle has a rich supply of muscle hemoglobin and cytochrome which also aid in its oxidative processes.

Methods.—In the study of metabolic activity of skeletal muscle, the standard procedure is to compare the chemical changes occurring in a stimulated muscle with those in a corresponding resting muscle. Unfortunately in the case of the heart, there is only one organ and that is rhythmically contracting. Therefore, it is very difficult to obtain the resting value of any chemical substance in the heart. Strips of ventricular muscle have been used, but their isolation involves considerable damage to the musculature. For these reasons,

cardiac metabolism is usually studied by analysis of the content of the material under consideration in the arterial and venous bloods and by the measurement of blood flow. These determinations give an accurate measure of the amount of material taken up by the heart but do not distinguish between storage and utilization. Special methods have been devised for the determination of the oxygen consumption of the heart. For small strips of tissue, or even for small hearts, the Warburg or Barcroft apparatus has been used (Fig. 291). For larger hearts, either the oxygen A-V difference is obtained, or the gaseous metabolism of a heart-lung preparation is determined. In the latter method a correction for the metabolism of the lungs which form a part of the biological system must be made.

Oxygen Utilization.—In any metabolic study, the first question to be solved is the amount of oxygen used, for this analysis gives a measure of the total metabolic activity. Numerous determinations of the oxygen consumption of the heart have been made, and the results have demonstrated that there are two chief factors which affect the amount used: the rate and the diastolic volume. In the frog's heart, Clark and White[259] observed that at the lower frequencies there was an increase of oxygen consumption proportional to the increase in rate but at the higher frequencies the total amount of oxygen used became less. In the dog's heart, Cohn and Steele[263] found that increasing the rate from 139 to 169 beats per minute changed the average oxygen consumption from 4.69 to 5.39 ml. per gram per hour. From these results and many others, it is obvious that an increase in rate affects oxygen consumption.

Increasing the diastolic volume also increases the oxygen consumption. Under these conditions the heart responds with a greater force of contraction (Starling's Law of the Heart, see page 346), and the additional force needs extra energy (Starling and Visscher,[274] Hemmingway and Fee[271]). Since the rate and the stroke output are the chief determining factors in the output of the heart, it becomes clear from these results that a change in cardiac output would demand a corresponding change in oxygen consumption.

Efficiency of the Heart.—The ratio between the output of energy by the heart and the input gives the efficiency of the heart as a pump. This factor has been determined by numerous observers using different formulas for the calculation of the output of work. All of these formulas contain two factors, the one involving the increase in pressure and the other depending on the movement of the column of blood. For example, the formula used by Evans[266] for calculating the work done by the heart is:

$$W = 7\left[\frac{QR}{6} + \frac{mV^2}{g}\right]$$

where W = work in kg. m.
Q = volume of blood in liters.
R = arterial pressure in m. of blood.
m = mass of blood in kg.
V = the mean velocity of blood at the aortic orifice during systole in m. per sec.
g = gravity constant = 9.8 m. per sec. per sec.

Regardless of the exact formula used, the results give an efficiency for cardiac muscle of the same order of magnitude as for skeletal muscle; i.e., from 10 to 25 per cent. The chief factor which affects efficiency is the amount of work which the heart does, because, when the output of work is low, the efficiency is also low. It increases with increasing amounts of work and then reaches a plateau. Additional amounts of work may even lower the efficiency. Visscher and his associates[265, 278] have been using the efficiency of the heart as a measure

of the activity of cardiac drugs. Their findings show that certain glucosides of digitalis have the ability to increase the mechanical efficiency of the failing heart.

Enzyme Systems of the Heart.—The heart muscle has a rich supply of muscle hemoglobin and cytochrome. Millikan[272] states that, as compared with other types of muscles, the hearts of large mammals have the most muscle hemoglobin, and that these hearts are characterized by having slow repetitive activity requiring the development of considerable force. The beef heart muscle is the favorite source of the biochemist for the isolation of cytochrome *c*. Since the oxygen consumption of the heart is decreased by cyanide, it may be concluded that the cytochrome-cytochrome oxidase system is involved in the activation and utilization of oxygen. Flavoprotein, the next component in the oxidative chain, is also present. In fact, Straub[276] has isolated a special heart flavoprotein which Corran, Green, and Straub[270] have shown to be active in the catalysis of the oxidation of DPN (coenzyme I) by methylene blue. The activity of this heart flavoprotein is such that one molecule will catalyze the oxidation of 8,500 molecules of DPN per minute. Numerous dehydrogenases are also present in heart muscle. The properties of lactate, malate, and β-hydroxybutyrate dehydrogenases from this source have been studied in detail by Green and his associates.[268-270] Succinate dehydrogenase (Stotz and Hastings[275]) is also present

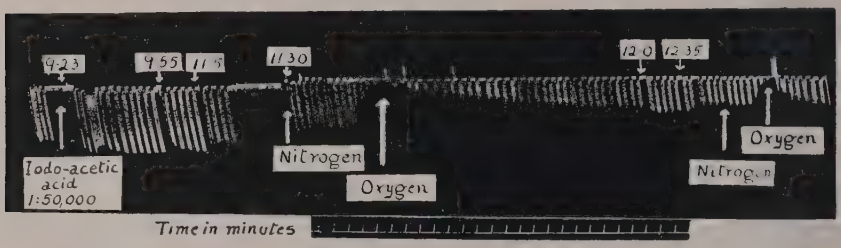

Fig. 292.—Effect of iodoacetate on frog's ventricle perfused under aerobic and anaerobic conditions. (From Clark, Eggleton, and Eggleton: J. Physiol. 75: 340, 1932.)

in considerable quantity. The heart is rich in DPN. It is quite obvious from the evidence at hand that heart muscle is well supplied with all the components of the oxidative systems as they are known at the present time.

Glycolysis of cardiac muscle as studied in enzymatic solutions proceeds along lines similar to those observed in skeletal muscle (Ochoa[273]).

Chemical Substances Used for Energy Production.—It has been known for a long time that glucose may be used by the contracting heart, the magnitude of the utilization depending on the amount of work that the heart does. Evans, Grande, and Hsu[267] found that the dog's heart uses an average of 70 mg. of glucose per 100 grams of heart muscle per hour working under normal arterial pressures. Wertherimer[280] and Visscher and Mulder[277] concluded that the utilization of glucose may not pass through a glycogen stage since they were unable to detect any decrease of glycogen in the heart working under aerobic conditions. Therefore, the utilization of blood glucose may be more direct than in the case of skeletal muscle. Under anaerobic conditions lactate is formed from glycogen. The fatigue level of lactate is much lower in cardiac muscle than in skeletal muscle: about 0.10 per cent for cardiac muscle in contrast to 0.30 per cent for skeletal. Under aerobic conditions, lactate may be

used by the heart (Evans et al.[267]). The heart muscle may also use pyruvate (Braun-Menendez, Chute and Gregory[257]) and β-hydroxybutyrate (Walters, Fletcher and Mirsky;[279] and Barnes et al.[256]). Claims have also been made that the isolated heart may use amino acids, but these views are based rather on calculations than on direct evidence (Clark, Gaddie and Stewart[260]).

A correlation of these numerous findings has been made by Clark and his associates[261] who studied the frog's heart by the aid of the inhibitory activity of monoiodoacetate. In the presence of oxygen, this substance does not change the capacity of the heart for work. In nitrogen, however, the ability of the heart to work is decreased when monoiodoacetate is present (Fig. 292). Since monoiodoacetate inhibits the breakdown of glycogen to lactate, it may be inferred from these results that this cycle plays no role under aerobic conditions but has an important emergency function under anaerobiosis. The mammalian heart is slightly affected by this poison even under aerobic conditions, and the activity of the heart may be restored by the addition of lactate, pyruvate, phosphoglycerate or propionate (Chang[258]). Under anaerobic conditions, phosphocreatine and adenylpyrophosphate are broken down in the heart.

Summary.—Though it is difficult to coordinate all of these findings, the following summary may be an aid. Oxidation of glucose is the normal source of energy for the heart. When the glucose content of the blood is low, β-hydroxybutyrate produced from fat in the liver may be used. Pyruvate and lactate may also be metabolized and may aid in giving energy to the heart during muscular exercise. Glycogen stores may be used during anoxia in the cardiac muscle. Thus the glycogen-lactate mechanism may be an emergency device for supplying energy under low oxygen concentrations or during temporary blocking of the coronary circulation. Amino acids are probably used following preliminary deaminization in the liver. The main source of energy for cardiac muscle is glucose.

CHAPTER LIII

GENERAL PROTEIN METABOLISM

A protein may be defined as a naturally occurring substance of high molecular weight which is composed of amino acid groups united together by an amide type of linkage. Since the animal body is unable to build proteins from inorganic substances and since proteins are being used continually in metabolism, they must be supplied from outside sources. It is also necessary to consider the chemical nature of the protein as well as the energy content since different proteins are not utilized to the same extent by the animal.

THE CHEMICAL NATURE OF PROTEINS

The predominant linkage in proteins is the so-called peptide linkage, the combination of the amino group of one amino acid with the carboxyl group of another. For example, the reaction between alanine and glycine to form the dipeptide, alanylglycine, is,

$$\underset{\text{alanine}}{CH_3CHNH_2CO\overset{\cdot\cdot}{O}H} + \underset{\text{glycine}}{H\overset{\cdot\cdot}{N}HCH_2COOH} \rightarrow \underset{\text{alanylglycine}}{CH_3CHNH_2CONHCH_2COOH} + H_2O.$$

Since the dipeptide contains a free amino group and a free carboxyl group, it is capable of combining with two more amino acids. This process may be continued until a chain of amino acids of indefinite length is formed.

The evidence in favor of the peptide type of linkage in the protein molecule has been summarized by Vickery and Osborne[350] as follows:

1. The peptide linkage accounts for the large amount of free amino nitrogen in the end products of protein hydrolysis which is not present in the native protein.

2. The biuret reaction, characteristic of proteins and proteoses, is given by compounds containing the peptide bond.

3. The synthetic polypeptides obtained by Fisher from the naturally occurring isomers of amino acids are hydrolyzed by some of the enzymes of the digestive tract.

4. Polypeptides have been found among the products of incomplete hydrolysis of proteins.

5. During the hydrolysis of proteins amino and carboxyl groups are liberated at an equal rate.

Although the evidence for the peptide linkage is very strong, there are various peculiarities in the behavior of proteins that cannot be explained on the basis of a large polypeptide molecule. The polypeptide theory does not explain denaturation of the molecule by alcohol or heat. Pepsin, the proteolytic enzyme of the gastric juice, does not liberate amino acids; it does not act on polypeptides nor on synthetically formed products of amino acids. The insolubility in water of many proteins cannot be predicted from the polypeptide theory. In order to explain these deviations from the usually accepted theory, numerous other hypotheses have been suggested. Sørensen,[340] for example, believes that proteins are made up of different components in dynamic equilibrium. Under certain conditions these components will combine in a definite manner,

and the separation of crystals may represent one combination while precipitation by salt may result in an entirely different one. Wrinch,[358] on the other hand, has developed the theory of a cycloid structure of the protein molecule. Bergmann and Niemann[297] have put forth the interesting idea that proteins consist of groups of units, each unit being composed of 288 amino acids arranged in recurring sequence. Regardless of the exact structure of any protein, amino acids must be regarded as the building stones in its formation, and they form the basis of protein metabolism.

The reactions that amino acids possess in common are due to the end groups containing the carboxyl and amino radicals, whereas the characteristic reactions of each of the amino acids depend on the chemical differences in the radicals attached to the end groups. The amino acids, with two exceptions, are α-amino acids. The exceptions are proline and hydroxyproline which are cyclic compounds and possess an α-imino group.

PROTEIN STARVATION

The first step in the study of protein metabolism is to determine the magnitude of the chemical breakdown in the tissues when no food is given; i.e., the endogenous protein metabolism. During the first few days of a fast, the amount of protein metabolized depends upon the glycogen content of the individual and the quantity of protein ingested before the starvation began. After an initial rapid decrease, there is a slow diminution of the nitrogen output. In the subject studied by Benedict[295] the total nitrogen eliminated on the last day of food was 11.54 grams and on the thirty-first day of the fast was 6.94 grams. Lusk[60] has calculated that the subject of Benedict's study lost 277 grams of nitrogen from his body or 16 per cent of the total amount present at the beginning of the fast. Junkersdorf and Lisenfeld[317] obtained much lower values in two subjects after a long period of starvation. In one subject, after a fast of 39 days, the output of urinary nitrogen was 4.81 grams per day. In the other subject this value had decreased to 3.32 grams on the thirty-eighth day of starvation.

Lower values of nitrogen output are obtained by feeding a subject a diet very low in protein but containing sufficient fat and carbohydrate to supply the necessary Calories. Mitchell and Hamilton,[284] summarizing values obtained on human subjects, reported variations from 3.8 to 1.75 grams of nitrogen per day. The amount of protein metabolized under these conditions has been termed the *minimum protein catabolism.* It represents the protein used in the wear and tear of the organs of the body and lost through the secretion of

TABLE LXVIII

LOSS OF WEIGHT OF ORGANS DURING A FAST (VOIT[354])

ORGAN	PERCENTAGE LOSS IN WEIGHT OF FAT-FREE TISSUE
Skeleton	5

Lungs	29

the digestive juices. A rough estimate of the loss of protein may be obtained by studying the loss in weight of various organs of the body during starvation. Voit[354] calculated this loss in the organ of a dog before and after a twenty-four-day fast (Table LXVIII).

Voit's findings suggest that there is a greater mobilization of protein from glands and skeletal muscle than from the heart and brain. It appears that during starvation the most vital organs live at the expense of those whose functions are not so necessary for life. Another observation showing that there is a transfer of nitrogenous substances from organ to organ in the body is the fact that the amino nitrogen of the blood does not decrease during prolonged fasting (Van Slyke and Meyer[349]).

NITROGEN EQUILIBRIUM

The next step in the study of protein metabolism is the determination of the quantity of protein which it is necessary to take in daily to balance the nitrogen lost in the excreta. One might expect that feeding an amount of protein which corresponds to the minimum protein catabolism would balance the output of nitrogen. This is not the case, as Voit and Korkunoff[355] demonstrated by feeding a dog meat from which most of the nitrogenous substances other than protein had been removed. Their results are given in Table LXIX.

TABLE LXIX

ESTABLISHMENT OF NITROGEN EQUILIBRIUM IN A DOG AFTER STARVATION
(VOIT AND KORKUNOFF[355])

FOOD	N IN FOOD	N IN EXCRETA	DIFFERENCE
Starvation	0	3.996	−3.996
100 grams meat	4.10	5.558	−1.458
140 grams meat	5.74	6.495	−0.755
165 grams meat	6.77	7.217	−0.447
185 grams meat	7.59	7.804	−0.214

230 grams meat	10.24	10.579	−0.339
360 grams meat	11.99	12.052	−0.062
410 grams meat	15.58	14.314	+1.266
360 grams meat	13.68	13.622	+0.058
Starvation 3rd day	0	4.026	−4.026

These experiments showed clearly that nitrogen equilibrium is reached only by feeding from three to four times the amount of protein that is metabolized during starvation.

A tremendous amount of work has been done in recent years to establish the amount of protein in the food necessary for the maintenance of nitrogen equilibrium in man. Experiments directed toward this end must be carried out over long periods of time, for nitrogen equilibrium is affected by previous protein ingestion. When a subject passes from a high to a low level, equilibrium is reestablished only after a long delay. Some of the protein already present in the tissues is metabolized and the amount of this is dependent on the previous diet. Borsook and Keighley[304] have termed the metabolism of the protein left from former ingestion the "continuing nitrogen metabolism" to distinguish it from the exogenous and the endogenous breakdown of protein. In a review of the data obtained from various sources Sherman[348] reports that nitrogen equilibrium is obtained by the daily ingestion of from 21 to 65 grams of protein,

the average being 44.4 grams. From his experiments on feeding bread and other grain products he found that 35 grams of protein from these sources are sufficient for actual maintenance requirements. To provide a margin of safety, he recommends 70 grams of protein a day. The lower level, the amount of protein that is just sufficient for the needs of the body, is called the *physiological protein minimum*. The amount that must be taken to insure an adequate supply is termed the *hygienic protein minimum* (Luck[42]). The average diet of man under normal conditions has sufficient protein to supply his needs. The diet of the United States soldier contains 131 grams of protein. The inhabitants of large cities ingest about 100 grams per person and hospital diets contain about the same amount. Since the various body tissues are made up of different proteins, a large variety of amino acids is necessary for the synthetic processes that occur in the formation of body proteins. Man has adjusted himself to this need by taking an excess of protein in his diet.

There are several factors which influence the level at which nitrogen equilibrium is established. If carbohydrate or fat is ingested with protein, the amount of protein needed for equilibrium is less than the amount necessary when protein is the only ingredient in the diet. Voit and Korkunoff[355] found that for every 100 grams of protein metabolized in starvation, 368 grams of protein alone, 157 to 193 grams of protein with fat or 108 to 134 grams of protein with carbohydrate had to be consumed in order to prevent loss of nitrogen to the body. Because of this fact the name "protein sparers" has been given fats and carbohydrates. Since such large amounts must be ingested to obtain the proper caloric value, it is practically impossible for man to subsist on protein alone. A subject fed on lean meat exclusively would be starved because he would oxidize his body stores of fat and carbohydrate in order to get the necessary calories. This fact forms the basis of treating obesity by diet.

Another factor in the maintenance of nitrogen equilibrium is the type of protein ingested. The tissues require an adequate supply of protein for their daily needs, but it is difficult to measure exactly this demand inasmuch as different tissues require different groups of amino acids for building their special proteins. The body may be forced to discard a large number of amino acids from a protein in order to obtain a sufficient amount of an individual acid. Thomas[344] determined the biological value of proteins from various sources by determining the amount of ingested protein required to balance the minimal nitrogen output. His results were as follows:

TABLE LXX

RELATIVE VALUE OF PROTEINS AS FOOD MATERIALS (FROM THOMAS[344])

SOURCE	PERCENTAGE UTILIZATION
Ox flesh	104.7
Milk	99.7
Fish	94.5
Rice	88.3
Cauliflower	85.8
Potato	78.9
Spinach	63.8
Flour	39.6

The results are given in terms of the amount of tissue protein spared by the ingestion of 100 grams of protein from the various sources. The high value for ox flesh, 104.7 per cent, may signify that other nitrogenous sub-

stances besides protein play an important role in metabolism. From the work of Thomas it would appear that protein from animal sources is far superior to that from vegetables. Other observers, however, have not obtained evidence of such marked differences between animal and vegetable protein. Hindhele[315] showed that nitrogen equilibrium may be obtained on a diet of potatoes which yields 25 grams or less of protein daily. Sherman reported that human

Fig. 293.—Photographs of rats of same brood on perfect diet (uppermost picture); on a maintenance diet but inadequate for growth (middle picture); and on a diet that was inadequate both for maintenance and growth. (From Mendel and Osborne.)

subjects can be kept in nitrogen equilibrium on diets of corn and oatmeal with 10 per cent milk protein. Such a diet furnishes only about 35 grams of protein per day. These values compare very favorably with similar experiments on nitrogen equilibrium in which the source of protein was of animal origin.

The variations in the ability of proteins to maintain the body in nitrogen equilibrium may be due to differences in chemical structure. For example, if

an animal is fed gelatin it metabolizes this substance completely and, in addition, uses some of the protein of its body. Gelatin, a derivative of collagen, does not contain tyrosine, cystine or tryptophane in appreciable amounts. When these amino acids are added to the gelatin, nitrogen equilibrium may be established (Kaufman[318]). Other proteins, such as gliadin and zein, are also deficient in certain amino acids (Table LXXI). These facts led to a determination of the indispensable amino acids without which growth is impossible. The experiments designed for this study consisted in feeding rats a diet to which mixtures of amino acids or various proteins were added. Using a diet in which zein was the sole source of protein, Willcock and Hopkins[357] observed that the rats lost

TABLE LXXI

THE AMINO ACID CONTENT (GRAMS PER CENT) OF A NUMBER OF PROTEINS, DETERMINED MAINLY BY ISOLATION METHODS (MITCHELL AND HAMILTON[284])

weight rapidly. When tryptophane was added to the diet the loss in weight was stopped but there was no growth (Fig. 293). In order to produce a gain in weight both tryptophane and lysine had to be added (Osborne and Mendel[335]). It was not necessary to give the missing amino acids in pure form since feeding

a diet containing protein with adequate amounts of lysine and tryptophan in the molecule produced the same effect. A graphic summary of this work is given in Figs. 294 and 295 and the diets used are given in Table LXXII.

The latest discovery in this field was made by Rose and his associates.[285] They fed rats nineteen pure amino acids in the same percentages that they

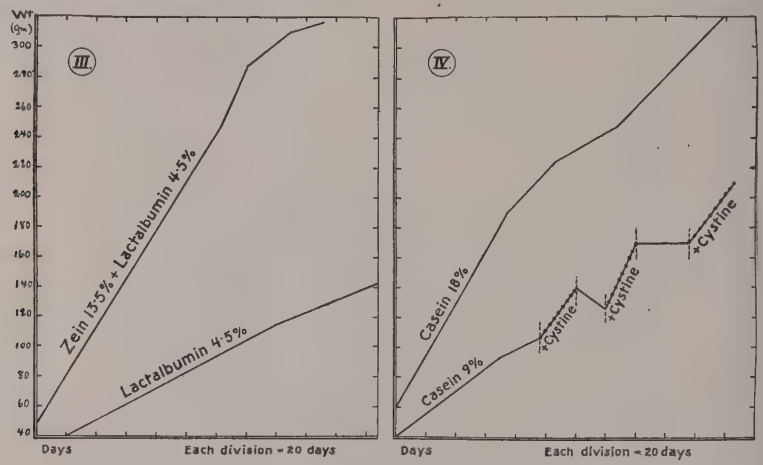

Fig. 294.—Curves of growth of rats on basal rations plus the proteins indicated. In curve III the effect of the addition of zein to an inadequate allowance of the perfect protein, lactalbumin, is shown; and in IV the effect of the addition of cystine to a deficient casein allowance. (From Lafayette B. Mendel and T. B. Osborne.)

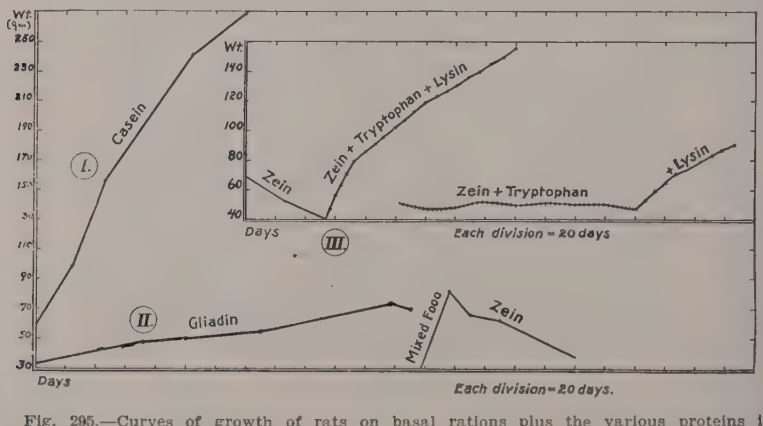

Fig. 295.—Curves of growth of rats on basal rations plus the various proteins indicated. The normal curve may be taken as that with casein (*I*). Adapted from Lafayette B. Mendel and T. B. Osborne.)

occur in casein. On this amino acid diet the rats lost weight but recovered it if 5 per cent casein, gliadin or gelatin was added. This result suggested that there was an unknown growth-promoting substance in the protein that was not present in the pure amino acids. Their search for this unknown compound resulted in the discovery of a new amino acid essential for growth, α-amino-β-

hydroxy-n-butyric acid, to which they gave the name "threonine." The synthetic compound prepared by Carter[308] has the same growth-producing power as the naturally occurring product. This discovery makes it possible for the first time to raise animals on purified amino acids and to determine experimentally the exact physiological importance of each acid by eliminating it

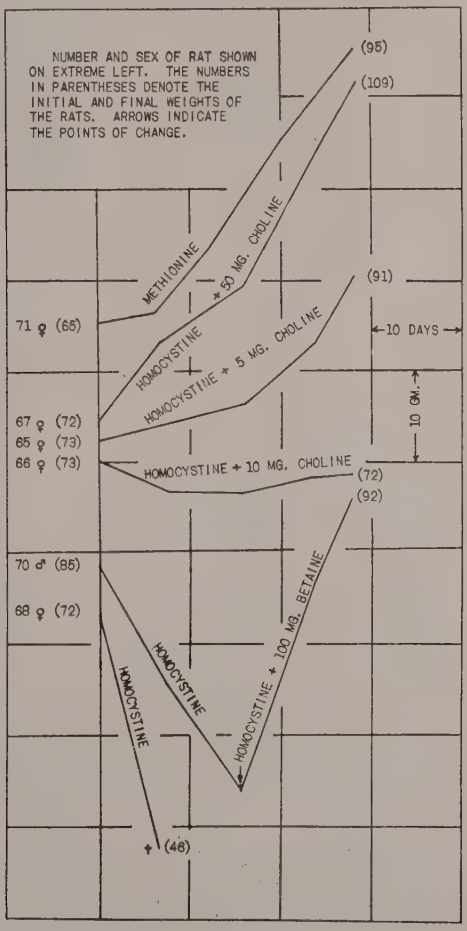

Fig. 296.—The effect of feeding homocystine, choline, and methionine on the growth of rats. (From du Vigneaud, et al.: J. Biol. Chem. 131: 57, 1939.)

from the diet. One of the difficulties in experiments of this type is that small traces of other amino acids may contaminate those of the essential group. Therefore, the use of only highly purified amino acids can give the final answer to this problem. The classification of the amino acids with respect to their growth effects is given in Table LXXIII.

TABLE LXXIII

FINAL CLASSIFICATION OF THE AMINO ACIDS WITH RESPECT TO THEIR GROWTH EFFECTS (ROSE[285])

INDISPENSABLE	DISPENSABLE
Lysine	Glycine
Tryptophane	Alanine
Histidine	Serine
Phenylalanine	Norleucine
Leucine	Aspartic acid
Isoleucine	Glutamic acid
Threonine	Hydroxyglutamic acid
Methionine	Proline
Valine	Hydroxyproline
Arginine	Citrulline
	Tyrosine
	Cystine

It is interesting to note that of the ten indispensable amino acids, both the d- and l- forms of tryptophane, histidine, phenylalanine, and methionine may promote growth, but only the natural or l-form of valine, leucine, isoleucine, lysine, and threonine have this function.

Another interesting fact is that homocystine cannot replace methionine. The livers of animals on a diet of homocystine were found to be fatty. On giving choline with homocystine, du Vigneaud and his associates[351, 352] found that not only were the livers free of fat, but the growth rate was normal; whereas on a diet of either homocystine or choline alone, growth was retarded (Fig. 296). These results demonstrate that choline is not only essential for the removal of fat from the liver (see Chapter LV), but also that it aids in the conversion of homocystine to methionine by its ability to act as a methylating donator. Both choline and methionine are lipotropic agents (see Chapter LV).

THE SPECIFIC DYNAMIC ACTION OF PROTEIN

After the ingestion of protein there is an increase in basal metabolism which amounts to about 30 per cent of the caloric value of the protein. This stimulating action of protein on metabolism is called its specific dynamic action. The fact that amino acids injected into the blood stream have an effect which is almost equal to that obtained by ingestion of an equivalent amount of protein shows that intestinal movements and the processes of digestion and absorption play a very minor part in raising the metabolism. Specific dynamic action is associated with changes in the amino acids in the liver, for Mann and his colleagues[329] have shown that there is no change in metabolism when the acids are injected into hepatectomized dogs. The extra heat production is associated with deaminization and urea formation and not with the complete combustion of the amino acids. Lusk observed a high specific dynamic action of amino acids in phlorizinized dogs in which, because of the action of the drug, part of the amino acid molecule is converted into glucose and lost in the urine. Not all the amino acids have the same specific dynamic action; for example, valine and histidine have none, while phenylalanine and tyrosine have a greater activity than alanine and glycine.

CHAPTER LIV

SPECIAL METABOLISM OF PROTEINS

The special metabolism of proteins involves the intermediate changes which take place between the ingestion of the protein molecule and the formation of the end products which are excreted. Some of these changes occur in the digestive tract and are due to the activity of the digestive enzymes (see Chapter LXVI).

Pepsin, the gastric protease, produces a slow and incomplete protein hydrolysis. The main products of the action of this enzyme are proteoses and peptones. The initial breaking of the protein molecule into shorter chains enables the intestinal enzymes to continue the fragmentation. The exact point of cleavage of the protein molecule in gastric digestion is not known. Torbet and Bradley[345] have presented evidence that the enzymatic activity may involve tyrosine. The amount of reactive tyrosine in casein is so small that it is impossible to estimate it with any degree of accuracy. However, after pepsin has acted on this protein, a markedly positive test is obtained. This fact indicates that tyrosine is converted into a reactive form by the action of pepsin. Practically no absorption of the split products of protein digestion occurs in the stomach.

The next step in the digestion of proteins occurs in the small intestine through the action of trypsin, an enzyme secreted by the pancreas, and erepsin, an enzyme produced by the small intestine itself. These enzymes rapidly liberate amino acids from the products of gastric digestion and the amino acids pass from the lumen of the intestine into the blood stream. There is some evidence that small amounts of proteins may pass through the intestinal wall. Wells[356] having fed a series of guinea pigs a diet of egg proteins, observed that these animals gave strong anaphylactic reactions when injected with egg albumen between the thirtieth and sixtieth days of feeding, but later showed only slight responses. He concluded that daily absorption of protein from the food rendered these animals hypersensitive to that protein with a subsequent development of immunity. Small amounts of polypeptides may also pass through the intestinal wall, for London and Kotschneff[325] have observed an increase in these compounds in the portal blood following ingestion of casein.

AMINO ACIDS IN BLOOD AND TISSUES

Although small amounts of proteins and polypeptides may pass through the intestinal wall, the chief products of protein digestion found in the portal blood are the amino acids. The evidence that free amino acids are present in the blood has been obtained by various modes of investigation. Abderhalden,[287] using large amounts of blood, was able to isolate and identify amino acids. Abel, Rowntree and Turner[290] developed an ingenious method for removing diffusible substances from the circulating blood by dialysis. This method, known as vividiffusion, consists in connecting the two ends of a cut artery of an anesthetized animal to a long collodion tube. The tube, coiled many times, is in an isotonic salt solution. As the blood passes through the tube, the diffusible constituents of the plasma pass into the surrounding fluid. In experiments it is possible to recover several of the amino acids from the salt solution, thus demonstrating that they are present free in the blood stream.

The methods of isolation and dialysis have shown that amino acids do occur in the blood. In order to follow the changes in these constituents, it is necessary to use quantitative methods. Levene and Van Slyke[323] developed a method for the determination of amino

nitrogen in the urine based on the fact that nitrous acid reacts with amino acids to liberate nitrogen gas according to the equation:

$$RNH_2 + HNO_2 = ROH + H_2O + N_2$$

This method has been employed also in blood studies. The most recent modification is one in which this reaction is adapted for use with the manometric method (Van Slyke[346]). The normal value for amino nitrogen in the blood varies from 5 to 8 mg. per 100 ml. of blood. This value is not affected by starvation, but does increase slightly after the ingestion of protein. Folin and Berglund[311] showed that in man the ingestion of 135 grams of gelatin increased the amino nitrogen from 6.7 mg. to 11.7 mg. per 100 ml. of blood.

Free amino acids are present also in the tissues. Van Slyke and Meyer[347] injected solutions of amino acids into animals and studied the disappearance of these acids from the blood and their accumulation in the tissues. They found that the amino acids are absorbed by the tissues without undergoing any immediate change. The greatest absorption occurs in the liver. The results of one of their experiments are given in Table LXXIV. Although the disappear-

TABLE LXXIV

EFFECT OF INJECTING 3.39 GRAMS OF AMINO NITROGEN INTO A DOG WEIGHING 7.4 KILOGRAMS (VAN SLYKE AND MEYER[347])

	BEFORE INJECTION	AFTER INJECTION
Liver	48	127
Muscle	46	78
Kidney	52	111
Blood	5.8	31.5

ance of the amino acids from the blood is rapid, it is never complete, for the blood contains these substances even during starvation. There are, therefore, two sources of the amino acids in the blood, the digested food proteins and the hydrolyzed tissue proteins. The concentration of amino acids is greater in the tissues than in the blood (Table LXXV). Van Slyke and Meyer suggest that this difference may be due either to mechanical adsorption or to the formation of loose molecular compounds between the amino acids and the tissue proteins.

THE FATE OF THE AMINO ACIDS

After the above study, Van Slyke and Meyer[349] determined the length of time the amino acids remain in various organs. Their results are given in Table LXXV.

TABLE LXXV

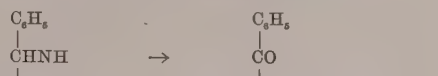
EFFECT OF INJECTING 2.70 GRAMS AMINO NITROGEN INTO A DOG WEIGHING 10.3 KILOGRAMS (VAN SLYKE AND MEYER[349])

TISSUE	AMINO ACIDS, MG. PER 100 GRAMS TISSUE		
	BEFORE	1 HR. AFTER	3 HR. AFTER
Muscle	47	68	67
Liver	–	79	34
Blood	8.2	18.3	12.4

Organs such as kidney, intestine, pancreas and spleen, gave results similar to those obtained on muscle. It was only in the liver that a rapid disappearance of amino acids occurred and this was associated with an increase in blood urea.

Studies of the blood and urine changes which occur in animals deprived of the liver have given additional evidence that this organ is the chief site of the metabolic changes undergone by the amino acids. Mann and his associates[329] have succeeded in keeping dogs alive for many hours in good condition following the extirpation of the liver. Amino acids accumulate and urea diminishes in the blood of these animals.

The Process of Deaminization.—The experiments of Van Slyke and of Mann and their associates have demonstrated conclusively that amino acids undergo metabolic changes in the liver. The main change is a process of deaminization, a splitting off of ammonia. It is agreed generally at the present time that this is an oxidative process. Neubauer[334] fed phenyl glycine to a dog and recovered phenylglyoxylic acid in the urine:



On the basis of this experiment and others, he concluded that amino acids are converted into the corresponding keto acids by an oxidative process which occurs according to the following equation:

$$RCHNH_2COOH + \tfrac{1}{2}\ O_2 \rightarrow RCOCOOH + NH_3.$$

The most recent evidence that the process of deaminization is an oxidative one has been obtained from a study of the oxygen uptake and ammonia production following the addition of amino acids to tissue slices. Krebs[320] observed that alanine added to liver and kidney tissue increases the production of ammonia and the consumption of oxygen. Negative results were obtained with other tissues. Later, Krebs[321] isolated two enzyme systems from the liver, one which deaminizes the dextro form and the other the levo form of the amino acids. Bernheim and Bernheim,[398] after isolating the enzymes which oxidize amino acids, found that one atom of oxygen is taken up for every molecule of amino acid oxidized. These results, obtained by different investigators with various techniques, show that the chief process is oxidative, although they do not eliminate the possibility that other types of deaminization take place in the liver. It is interesting to note that conclusive evidence that the kidney is able to deaminize amino acids was obtained only after the introduction of the tissue slice method into metabolic experimentation.

Another interesting mechanism for deaminization is the transfer of amino groups to keto acids discovered by Braunstein and Kritzmann.[307] They showed that a reversible reaction takes place according to the following equation:

glutamic acid + pyruvic acid = α-ketoglutaric acid + l-alanine.

Amino acids give up readily their amino group to a ketoglutaric acid to form glutamic acid. This reaction forms a possible link between protein and carbohydrate metabolism, and explains how some of the dispensable amino acids may be formed. It also demonstrates the possibility of a rapid interchange of amino nitrogen. Direct proof of this interchange has been supplied by Schoenheimer and his associates. By feeding tyrosine containing heavy nitrogen, N^{15}, they showed that ten days later heavy nitrogen was contained in the monoaminodicarboxylic acids, in arginine, and in histidine. With this same tag,

they also demonstrated that heavy nitrogen in ingested ammonium citrate soon finds its way into amino acids, demonstrating that ammonia enters into the synthetic formation of these acids.

Oxidation of Keto Acids.—One of the end products of oxidative deamination is a keto acid which the animal is capable of handling by oxidation or conversion to sugar. Keto acids are oxidized readily to carbon dioxide and water. It is supposed that this process occurs by oxidation of the α-carbon to a carboxyl group. Following the liberation of carbon dioxide from this molecule, a fatty acid is formed. The fatty acid is oxidized according to the usual pathways for the breakdown of these substances (see Chapter LV).

The reactions are as follows:

$$RCH_2CHNH_2COOH + \tfrac{1}{2}\ O_2 \rightarrow RCH_2COCOOH + NH_3$$
$$RCH_2COCOOH + \tfrac{1}{2}\ O_2 \rightarrow RCH_2COOH + CO_2$$
$$RCH_2COOH + nO_2 \rightarrow xCO_2 + yH_2O$$

Keto acids such as pyruvic may also be converted into lactic acid.

Conversion of Amino Acids Into Sugar.—The animal body is able to convert some of the amino acids into sugar. This process has been studied by feeding the acids to an animal made diabetic by the removal of the pancreas or by injection of phlorizin. Dakin[309] has summarized the results of experiments of this type as follows:

1. The amino acids which yield glucose freely in the diabetic organism are all those, except valeric, which contain two, three, four or five carbon atoms.

2. Arginine is the only amino acid with more than five carbon atoms which may furnish glucose freely.

3. All the straight chain amino acids except lysine yield sugar.

4. The amino acids with branched chains, including valine, leucine and isoleucine, furnish little or no sugar.

5. Proline is the only cyclic amino acid known to yield glucose.

The exact mechanisms involved in the conversion are not known. The fact that simple keto acids, such as pyruvic, formed in the process of deamination are converted readily into glucose in the animal body may be of significance in this connection.

Conversion Into Fat.—The process of partial oxidation following deamination gives a fatty acid. This suggests the possibility that amino acids may play a role in fat storage. Experimental evidence for this conversion is not as convincing as that for the transformation of amino acids into glucose. Addis, MacKay and MacKay[291] found very little deposition of fat in rats fed a high protein diet. Indirect evidence for conversion has been obtained from a study of the respiratory exchange during the feeding of high protein diets. Atkinson, Rapport and Lusk[293] determined the respiratory quotient and the retention of carbon in dogs following the ingestion of large amounts of meat. They calculated that if all the retained protein carbon were deposited in the form of glucose the heat production would be greater than that actually observed. Therefore it must have been deposited as fat or as a mixture of fat and carbohydrate. The nonprotein respiratory quotients found in these experiments indicated that protein was being converted into fat. If all the assumptions made

by these authors are accepted, their experiments do indicate a transformation of protein into fat under conditions of excessive feeding of proteins. More direct evidence is needed on this point.

Synthesis of Proteins.—Amino acids are utilized in the building of proteins. During pregnancy and growth additional proteins are formed from the amino acids taken from the blood. During lactation large amounts of milk proteins are formed. These proteins must come from the amino acids transported by the blood. The exact mechanism of protein synthesis is very obscure. Alcock,[292] in a review of the scanty evidence bearing on this subject, suggests that the amino acids are taken up by the tissues and then broken down into a common unit which provides the basis for the synthesis of protein. After the construction of this basic molecule, the protein molecule is differentiated by the addition of other molecules. The exact nature of the final product is dependent on the tissue in which the protein is formed.

It may be that the liver or intestines change the amino acids which pass through these organs on their way to the tissues. The following facts point to a dominant control by the liver over the escape of amino acids into the blood stream. London and his associates[324] have found an increase in polypeptides in the blood coming from the liver during protein digestion. Injection of tryptophan into rats on a diet deficient in this substance does not improve the condition of these animals (Alcock[292]). Seth and Luck[337] found that after absorption from the intestine glutamic and aspartic acids do not produce a rise in blood amino nitrogen, while glycine and alanine give pronounced changes. Concerning the mechanism of this control and the liberation of amino acids in time of need, there is no available information at the present time.

THE END PRODUCTS OF PROTEIN METABOLISM

Analysis of the nonprotein nitrogen of the blood shows that it is chiefly derived from urea, amino acids, uric acid, creatine, creatinine, and a residue which is designated the "undetermined nitrogen." The quantity of nonprotein nitrogen of the whole blood of normal individuals averages 35 mg. per 100 ml., the nitrogen of urea accounting for one-half of the total. Wu[359] has investigated the partition of these substances between the corpuscles and plasma and his results are given in Table LXXVI.

TABLE LXXVI

NONPROTEIN NITROGEN SUBSTANCES IN PLASMA AND CORPUSCLES (From Wu[359])

	AVERAGE VALUES (MG. PER 100 ML.)	
	CORPUSCLES	PLASMA
Total Nonprotein N	49.3	28.80
Urea N	17.1	19.30
Uric Acid	1.93	3.92
Total Creatinine	8.32	1.47
Preformed Creatinine	2.48	1.24
Amino Acid N	9.47	5.52

In the urine, urea nitrogen may account for 80 per cent of the total nitrogen although the value varies with the amount of protein in the diet. Smith[339] has described the distribution of the nitrogenous compounds in the

urine of a man on a normal diet and compared it with that of the same individual after he had been on a low protein diet. His findings are given in Table LXXVII.

TABLE LXXVII

NITROGENOUS SUBSTANCES (GRAMS PER DAY) IN URINE OF MAN ON NORMAL AND LOW PROTEIN DIET (From Smith[339])

	NORMAL DIET	LOW PROTEIN DIET	
		AFTER 16 DAYS	AFTER 25 DAYS
	Gm.	Gm.	Gm.
Total N	9.32	2.37	1.58
Urea N	7.62	1.08	0.35
Ammonia N	0.41	0.31	0.23
Creatinine N	0.63	0.56	0.56
Uric Acid N	0.11	0.10	0.11
Undetermined N	0.55	0.32	0.33

Volume of urine (ml.)	1425	415	970

These results illustrate several important facts in connection with protein metabolism:

1. The total amounts of nitrogen and of all the nitrogenous metabolites, except creatinine, diminish during partial protein starvation.

2. The output of urea decreases relatively more than the output of total nitrogen. Therefore the relative amounts of the other nitrogenous metabolites increase.

3. The output of creatinine is unchanged.

4. The total amount of urine diminishes. This fact demonstrates that the end products of protein metabolism exert a diuretic action.

Urea.—The high concentration of urea in the blood and urine suggests that this substance is the chief end product of protein metabolism. Chemically, urea [$CO(NH_2)_2$] is a diamide of carbonic acid, having 46.6 per cent nitrogen in the molecule. In the preceding chapter evidence was presented that deamination of the amino acids occurs in the liver with production of urea. Krebs and Henseleit[322] have proposed an attractive theory for the conversion of ammonia to urea in this organ. They showed that the addition of ornithine or citrulline to liver slices increases the formation of urea, especially in the presence of ammonia. The concentration of ornithine did not change but the amount of citrulline decreased. From these and other observations Krebs and Henseleit concluded that ammonia is converted to urea through the following reactions:

1. $RCH_2NH_2 + CO_2 + NH_3 \rightarrow RCH_2NHCONH_2 + H_2O$ [R = $CH_2CH_2CHNH_2COOH$]
   ornithine citrulline

2. $RCH_2NHCONH_2 + NH_3 \rightarrow RCH_2NH.C(:NH)NH_2 + H_2O$
   citrulline arginine

3. $RCH_2NH.C(:NH)NH_2 + H_2O \rightarrow RCH_2NH_2 + CO(NH_2)_2$
   arginine ornithine urea

Apparently, other tissues do not have the property of converting ammonia into urea. Bollman and Mann[302] have demonstrated that after removal of the liver there is cessation of urea formation, and that urea is not formed when ammonia is injected; the ammonia escapes into the urine and tissues where it is

found as ammonium salts. Krebs and Henseleit,[322] using tissue slices, also observed that the liver is the only organ in the body capable of converting ammonia into urea.

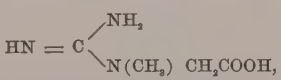
Ammonia.—Although the content of ammonia in the blood is very low (0.1 mg. per 100 ml.) the amount found in the urine may be as high as 1.0 gram per day. The reason for this difference is that ammonia is formed in the kidney. The best evidence for this formation has been obtained by Nash and Benedict[333] who observed that the ammonia content of the renal vein is higher than that of the systemic arterial or venous blood. It was shown also that the injection of acid or alkali, which is known to change the amount of ammonia in the urine, has no effect on the ammonia content of the systemic circulation. Nash and Benedict postulated that urea is the source of urinary ammonia. Another source may be the deaminization of amino acids in the kidney, for Krebs[321] has shown that kidney slices have the power to split off the amino group from amino acids and so produce ammonia. On the other hand, in dogs from which the liver had been removed, Bollman and Mann[302] were unable to show that amino acids have any effect on ammonia formation, whereas the administration of urea was accompanied by a marked rise in the urinary ammonia.

Urinary ammonia plays an important role in the regulation of the acid-base balance of the body. Following injection of acids or the production of fixed acids in the body, ammonia formation by the kidney is increased. Assuming that the ammonia comes from urea, the following reaction may take place:

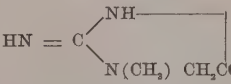
$$(NH_2)_2CO + 2NaCl + H_2CO_3 + 2H_2O \rightarrow 2NH_4Cl + 2NaHCO_3.$$

The ammonium chloride is eliminated by the kidneys, leaving the sodium bicarbonate available for neutrality regulation. Alkalosis produced by bicarbonate administration or hyperventilation reduces the output of ammonia in the urine.

Creatine and Creatinine.—These substances are products of nitrogenous metabolism, although some of the creatine and creatinine present in the food may appear in the urine. Creatine (methyl guanidine acetic acid),



is found chiefly in the muscles, although small traces may be demonstrated in the brain, testes, and other organs. Creatinine, an anhydride of creatine,



is related to creatine both chemically and physiologically. By means of his colorimetric method for the determination of creatinine, Folin[310] found that in any one individual the output of this substance is constant. The quantity of creatinine excreted does vary with different persons. The chief factor is the weight of the individual. Therefore, it is convenient to express the output of this substance in terms of the *creatinine coefficient.* This coefficient is obtained by dividing the amount of creatinine in milligrams excreted in twenty-four hours by the body weight in kilograms. In men the coefficient varies be-

tween 20 and 26; in women lower values ranging from 14 to 22 are found. The difference depends on the relative degree of muscular development in the two sexes.

Following the ingestion of creatinine, the greater portion of it may be recovered from the urine, whereas creatine must be taken in large quantities before any appears in the urine. When creatine does come through in the urine under these conditions, it is accompanied by a small amount of creatinine (Benedict and Osterberg[296]). From these experiments it appears that the body is able to store or oxidize creatine and to convert part of it to creatinine. Creatine is not found in the urine of adults on a normal diet, but it is a normal constituent of the urine of children and it appears during starvation.

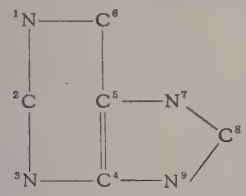
Many theories have been proposed to explain the origin of creatine in the body. Beard and Barnes[294] fed proteins and various amino acids to rats, and found that these substances increased the creatine content of the muscles and augmented the creatinine output. They concluded that creatine formation and creatinine excretion are directly due to the feeding of these large quantities of proteins and amino acids or that these substances indirectly stimulate the mechanism of formation of these substances. In a discussion of this work Rose[336] comes to the conclusion that the latter explanation is the correct one and that the apparent stimulation is of a nonspecific character. In patients suffering from progressive pseudohypertrophic muscular dystrophy, ingested creatine is recovered quantitatively in the urine. Brand and his associates[306] reported that feeding glycine to these patients increases creatine excretion 40 per cent above the control level. Abderhalden and Buadze[288] claim that nucleic acids and histidine are effective in raising the output of creatinine. It is impossible to determine by such experiments whether the extra creatine and creatinine are formed from the ingested substances or whether they are produced by some indirect process.

The use of tagged molecules has been extremely valuable in the study of creatine metabolism. Bloch and Schoenheimer[299] have shown that the administration of isotopic nitrogen in creatine was followed by the appearance of isotopic nitrogen in the creatinine of the urine. When isotopic nitrogen in creatinine was given to an animal, all of the isotopic material was recovered in the creatinine of the urine and none was found in the creatine of the body. These facts demonstrate that the reaction of creatine to creatinine is irreversible in the animal body. Heavy nitrogen in glycine or ammonium citrate fed to animals has been recovered in the glycine moiety of creatine (Schoenheimer et al.[300]), and N^{15} in the amidine group of arginine has been found transferred to the creatine molecule (Block and Schoenheimer[301]). By placing deuterium in the methyl group of methionine, du Vigneaud and his associates[353] have proved that this group is removed biologically to form the methyl group in creatine. Glycocyamine added to kidney and liver slices increased the production of creatine by these tissues (Borsook and Dubnoff[305]). These results make the origin of creatine clear; it is derived from the methyl group of methionine, the amidine group from arginine and the glycine part from glycine fed or produced in the body.

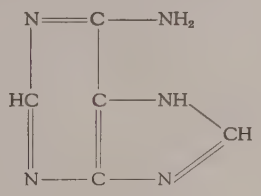
The importance of phosphocreatine in muscular contraction is discussed in Chapter LII.

Uric Acid.—The amount of uric acid found in the urine of man is very small; it varies from 2.5 to 5 mg. per 100 ml. In birds and reptiles this sub-

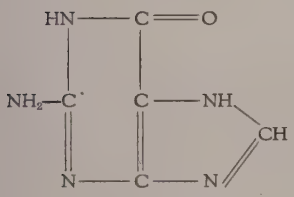
stance takes the place of urea as the chief end product of protein metabolism. For example, from 60 to 70 per cent of the nitrogen excreted in the urine of the goose is in the form of uric acid. This fact led to the idea that in man uric acid may be formed from proteins. Modern work has shown, however, that most, if not all, of the uric acid in the urine of man comes from the metabolism of purines and not from the breakdown of protein. The source of purines in the body is the nucleoproteins, which are complex substances composed of proteins and nucleins. The nucleins, in turn, may be hydrolyzed into nucleic acids and protein. Nucleic acids are found in the nuclei of cells; they probably do not occur in the cytoplasm. A nucleic acid is chemically complex, being composed of phosphoric acid, a pentose and purine base or pyrimidine. In the animal body three purine bases have been found: adenine, guanine, and hypoxanthine. These substances are readily oxidized to uric acid. The chemical similarity between these compounds and uric acid are shown by their structural formulas:



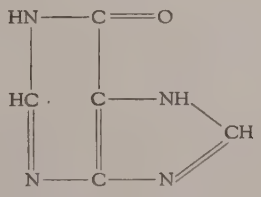
hypothetical purine skeleton



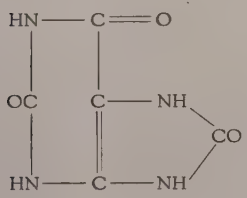
adenine
(6—aminopurine)



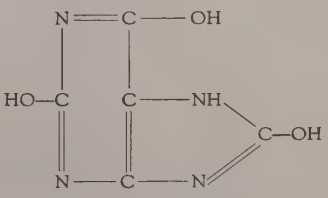
guanine
(2—animohypoxanthine)



hypoxanthine
(6—oxypurine)



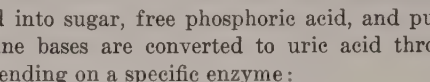
uric acid (lactim structure)



uric acid (lactam structure)

Two formulas are given for uric acid, the lactim and lactam; uric acid in solution may be made up of a mixture of these two forms.

Catabolism of Nucleic Acid.—Gastric and pancreatic juices split off the proteins attached to the nucleic acids and the intestinal secretions complete the splitting of the acid into sugar, free phosphoric acid, and purine bases. After absorption the purine bases are converted to uric acid through a number of steps, each step depending on a specific enzyme:



Bollman and Mann[303] have shown that the uric acid content of the blood increases after removal of the liver. Therefore, these reactions may take place elsewhere, probably chiefly in the muscles.

Excretion of Uric Acid.—A subject on a purine-free diet continues to excrete uric acid. This is derived from the purine constituents of the animal's own tissues and is referred to as *endogenous* uric acid. The endogenous purine metabolism is affected slightly by alteration of the protein intake. Folin, Berglund and Derick[312] have shown that high protein feeding increases the output of uric acid in the urine but decreases the blood uric acid. They concluded that the protein ingestion acts by accelerating the activity of the kidney in getting rid of the uric acid rather than by increasing its production. The source of the endogenous uric acid has been placed in the muscles, although Krafka[319] has presented evidence that it may come from destruction of the nuclei in the formation of red blood cells. In dogs he found a marked increase in the output of uric acid after hemorrhage, the output decreasing as the number of normal (nonnucleated) red blood cells increased. Confirmatory evidence was obtained by finding an increase in uric acid excretion when anemia was produced by phenylhydrazine hydrochloride.

The *exogenous* uric acid comes from the metabolism of the ingested purines. Thymus, pancreas, liver, and kidney contain considerable amounts of purine bases. Other sources are coffee, cocoa, and tea which contain methyl-purine derivatives. Some of the vegetables, peas, beans, and spinach, contain considerable amounts of these substances. Part of the ingested purine is excreted as uric acid; the amount depends on the particular purine base. Mendel and Lyman[332] showed that 64 per cent of ingested hypoxanthine, but only 37 per cent of adenine, is converted into uric acid. The remainder is apparently converted into unknown compounds. Compounds containing adenine have been shown to play an important role in the chemistry of muscular contraction (see Chapter LII).

THE CONTROL OF PROTEIN METABOLISM

Much less is known of the control of protein metabolism than of the control of carbohydrate or of fat metabolism. When insulin is injected into a diabetic, there is a fall in urinary nitrogen. This may be interpreted as a shift in metabolism from protein to carbohydrate under the influence of this hormone. However, Janney and Shapiro[316] have shown that insulin and glucose in a normal human subject have a greater sparing action of protein than glu-

cose alone. Mirsky[330] using, as an index of protein utilization, the nonprotein nitrogen concentration in the blood after nephrectomy, demonstrated a decrease in the nonprotein nitrogen and amino acid concentrations. MacKay, Barnes and Bergman[328] have shown a greater retention of nitrogen in rats injected with insulin. These results indicate that insulin either increases the utilization by the tissues of amino acids, for protein formation decreases the rate of deamination in the liver, or is operative by use of both processes.

The pituitary may play a role in protein metabolism. Extract of the anterior pituitary gland causes a fall in the nonprotein nitrogen of the blood (Teel and Watkins[343]) and a retention of nitrogen (Gaebler and Price[314]). Mirsky[331] showed that anterior pituitary extract increases the breakdown of protein in the muscle of a depancreatized animal. He assumes that in the intact animal the pituitary extract calls forth extra insulin, which counteracts the direct effect of the anterior pituitary extract on the muscle protein and which may decrease the utilization of amino acids in the liver. Additional evidence that the pituitary gland may control protein metabolism is furnished by a study of the blood sugar level in an hypophysectomized dog. In starvation, the blood sugar falls more rapidly than in a normal animal, but on a protein diet it is maintained (Soskin et al.[341]). This indicates that an animal without its pituitary gland is unable to mobilize its own amino acids for conversion into sugar but can use exogenous protein for that purpose. Adrenal cortical hormone also has an effect on protein metabolism, since gluconeogenesis is accelerated (see Chapter LI).

CHAPTER LV

THE METABOLISM OF FATS

GENERAL METABOLISM OF FATS

The fats have many important functions in the animal body. Their chief use is to serve as a store of potential energy. In this capacity they may be deposited by the body in almost unlimited amounts for utilization during future periods when the intake of food material is diminished or the expenditure of energy is increased. In addition, fats enter into the composition of many of the important structures of the body such as the nerve sheaths. They act as carriers for several of the vitamins and some of the fats are themselves essential for life. The sterols, substances related to fats, enter into the chemical constitution of hormones, vitamins and bile salts.

Classification of Fats.—Under the general heading of *lipids* the fatty acids and the compounds of fatty acids used in animal metabolism have been grouped by Bloor[361] as follows:

A. Substances having the following characteristics:
   1. Insolubility in water and solubility in fat solvents (e.g., ether, chloroform and benzene).
   2. Relationship to the fatty acids as esters, either actual or potential.
   3. Utilization by living organisms.

B. The following substances possess these qualifications:
   1. *Simple lipids:* Esters of the fatty acids with various alcohols.
      a. *Fats;* esters composed of fatty acids and glycerol.
      b. *Waxes;* esters composed of fatty acids and alcohols other than glycerol.
   2. *Compound lipids:* Esters of the fatty acids containing groups in addition to an alcohol and fatty acids.
      a. *Phospholipids:* Substituted fats containing phosphoric acid and nitrogen. Examples, lecithin and cephalin.
      b. *Glycolipids:* Compounds of fatty acids containing a carbohydrate and nitrogen but no phosphoric acid. Example, the cerebrosides.
      c. Aminolipids, sulfolipids, etc.: Groups which are not characterized sufficiently for classification.
   3. *Sterols:* Large molecular alcohols, found in nature combined with fatty acids. Example: cholesterol.

Absorption of Fats.—Following ingestion fat is broken down into glycerol and fatty acid by the action of the enzymes present in the gastric, pancreatic and intestinal juices. The major portion of this splitting occurs in the intestine where digestion and absorption of fat are aided by the bile. In the duodenum, the free fatty acids are neutralized by the alkaline secretions to form soaps. During the passage of the fatty acids and glycerol through the intestinal wall these substances are reunited to form neutral fat (see Chapter LXVIII). This

process may involve an intermediate phosphorus compound, for, as Sinclair[404] has demonstrated, there is a change in the phospholipid fatty acids of the intestinal mucosa while fat is being absorbed. Whether or not this is an obligatory intermediate between the fatty acid and neutral fat is not known. The fats are transported chiefly through the thoracic duct to the blood stream although other channels are present (Lee[390]).

Blood Fat.—The various lipids in the blood have been studied by several investigators. A summary of these results is given in Table LXXVIII. The com-

TABLE LXXVIII

LIPIDS IN NORMAL HUMAN PLASMA (FROM PAGE, KIRK, LEWIS, THOMPSON, AND VAN SLYKE[394]) THE RESULTS ARE IN MG. PER 100 ML. OF PLASMA

AUTHORS	NUMBER OF SUBJECTS	CHOLESTEROL TOTAL	CHOLESTEROL FREE	PHOSPHATIDES	NEUTRAL FATS	TOTAL LIPIDS

Boyd, 1935	8	177	52	185	131	582
Van Slyke, *et al.*, 1935	66	232	82	181	225	735

position and the amount of blood fat are affected by the ingestion of this foodstuff. Leathes and Raper[388] have summarized the changes in blood fat occurring after a meal as follows: (a) the amounts of fatty acids in different combinations increase in plasma and corpuscles; (b) the amount of cholesterol tends to increase up to a certain maximum; (c) the amount of phospholipid increases, and it appears that the newly formed phospholipid is made from the absorbed fatty acids; (d) the cholesterol esters increase, chiefly in the corpuscles.

Storage of Fat.—The distribution of reserve fat has been studied quantitatively by Mendel and his associates;[397] their results are given in Table LXXIX. The amount of fat in these depots depends mainly on the quantity

TABLE LXXIX

DISTRIBUTION OF RESERVE FAT IN A RAT (FROM REED, YAMAGUCHI, ANDERSON AND MENDEL[397])

	PROPORTION TO TOTAL FAT (PER CENT)
Subcutaneous	50
Genital	20
Perirenal	12
Mesenteric	10
Intermuscular	5
Omental	3

of fat in the diet and the demand for energy. Reed, Anderson and Mendel[396] found that in rats more fat is stored on a diet rich in this substance than on one rich in carbohydrate, while exercise decreases the total amount but increases the relative amount of intermuscular fat. The type of fat in the storage depots varies with the type fed the animal. Lebedeff[30] starved two dogs until their normal supply of fat was depleted. To one of these dogs he fed mutton tallow and to the other linseed oil and later found that the fat laid down by these animals resembled the fat ingested by each. Other methods have been devised to study fat storage. For example, phenyl or a halogen groups may be intro-

duced into the fatty acids ingested and later these may be detected in the storage depots. The most recent experiments of this type have been made by Schoenheimer and his associates[401] who substituted deuterium (heavy isotope of hydrogen) for some of the hydrogen of the fat molecule. Their results showed that most of the ingested fat containing deuterium found its way to the fat depots while only a small fraction was present in the cells of the internal organs. They concluded that the ingested fat is deposited before use. It may be, however, that the animal is not able to oxidize fats containing foreign substances as readily as the normal fats and, therefore, these fats are shunted into the fat storage depots.

All of the fat does not disappear from the tissues during starvation. This fact has led to the concept that a certain amount of the fat in a tissue is an essential part of that tissue while the remainder is present as storage material. The essential portion is constant in amount while the storage fat varies with the amount present in the diet and with the metabolic activity of the issue.

The liver may act as a temporary storage place for fat as well as for carbohydrate. During this period of storage, the liver converts the fatty acids into lecithin which may be easily transported to the fat depots. Sinclair[404] has described two types of phospholipids in the liver: the one containing highly unsaturated fatty acids, the other containing ordinary food fats. He has proposed the interesting theory that the first is the structural phospholipid, and the second is the metabolic phospholipid which has to do with transport and metabolism of the fat obtained from food. Chaikoff and his associates[375] have studied the distribution of radioactive phosphorus (page 723) after ingestion of labeled phosphate. Immediately after ingestion, the intestinal tract, liver, and kidney show the highest content of phospholipid containing the radioactive phosphorus; however, the brain does not reach its maximal content until 200 hours later. These results indicate that the liver and intestine have the ability to form phospholipids quickly. *In vitro* studies with radioactive phosphorus have given a similar result.[398]

Under certain conditions, large amounts of fat accumulate in the liver. This fat is neutral fat, for the content of phospholipid during its accumulation remains constant. Bloor[362] has summarized the circumstances under which fat accumulates as follows: (1) in depancreatized dogs on certain mixed diets with insulin treatment; (2) after high-fat, low-protein diets; (3) after cystine feeding, but not after methionine feeding; (4) after cholesterol feeding; (5) during fasting if there is available fat in the depots; (6) after anterior pituitary extract injections; and (7) in the hen at onset of sexual maturity. The control of some of these processes will be discussed in the next chapter.

Cholesterol.—The sterols have many important functions in the body, for they enter into the composition of hormones, vitamins, and the cellular structure of some organs. They aid also in the saponification of fats by the action of bile. Some of the sterols, such as cholesterol, can be formed by the body from fats, because, as Eckstein[381] has shown, more cholesterol is formed on a high fat diet than on a low. Schoenheimer and Breusch[400] found that mice on a diet of bread synthesize as much cholesterol in a month as was initially contained in their bodies. The amount formed depends on the need, for when large amounts of cholesterol are given, there is a breakdown of this substance in the animal body.

SPECIAL METABOLISM OF FATS

There are four different pathways for oxidation of fat: β-oxidation, ω-oxidation; combined β- and ω-oxidation, and desaturation.

β-Oxidation.—By feeding various phenylated compounds of fatty acids, Knoop[386] succeeded in obtaining derivatives of the lower fatty acids. Depending on the length of the chain of the fatty acid either hippuric or phenaceturic acid appeared in the urine. These compounds are formed by the reaction of glycine with benzoic or phenylacetic acid:

1. $C_6H_5COOH + CH_2NH_2COOH \rightarrow C_6H_5CONHCH_2COOH + H_2O$
(benzoic acid) (glycine) (hippuric acid)

2. $C_6H_5CH_2COOH + CH_2NH_2COOH \rightarrow C_6H_5CH_2CONHCH_2COOH + H_2O$
(phenylacetic acid) (glycine) (phenaceturic acid)

The results obtained by Knoop when various phenyl derivatives of fatty acids were fed are given in Table LXXX. In these experiments fatty acids with an

Table LXXX

Oxidation Products of Phenyl Fatty Acids (From Knoop[386])

ACID FED		OXIDATION PRODUCT	EXCRETED AS
Benzoic acid	C_6H_5COOH	not oxidized	Hippuric acid
Phenylacetic acid	$C_6H_5CH_2COOH$	not oxidized	Phenaceturic acid
Phenylpropionic acid	$C_6H_5CH_2CH_2COOH$	C_6H_5COOH	Hippuric acid
Phenylbutyric acid	$C_6H_5CH_2CH_2CH_2COOH$	$C_6H_5CH_2COOH$	Phenaceturic acid
Phenylvaleric acid	$C_6H_5CH_2CH_2CH_2CH_2COOH$	C_6H_5COOH	Hippuric acid

odd number of carbon atoms gave rise to hippuric acid while those with an even number formed phenaceturic acid. Knoop explained these results by assuming that oxidation takes place in steps, each step consisting in throwing off the two carbon atoms adjacent to the — COOH group (β-oxidation):

$C_6H_5CH_2CH_2CH_2CH_2COOH \rightarrow C_6H_5CH_2CH_2COOH \rightarrow C_6H_5COOH$
(phenylvaleric acid) (phenylpropionic acid) (benzoic acid)

Additional evidence that this type of oxidation takes place was given by Embden[382] who found in liver perfusion experiments that fatty acids with an even number of carbon atoms give rise to acetoacetic acid while those with an odd number disappear. His results are given in Table LXXXI.

Table LXXXI

Acetoacetic Acid Formation From Fatty Acids (From Embden[382])

NORMAL FATTY ACID	NO. OF C ATOMS	FORMATION OF ACETOACETIC ACID
Acetic acid	2	variable
Propionic acid	3	–
Butyric acid	4	+
Valeric acid	5	–
Caproic acid	6	+
Heptylic acid	7	–
Octoic acid	8	+
Nonoic acid	9	–
Decoic acid	10	+

These results were explained by assuming, as Knoop had done, that oxidation takes place at the β-carbon atom and so gives rise to acetoacetic acid when the compound contains an even number of carbon atoms:

1. $CH_3CH_2CH_2COOH \rightarrow CH_3COCH_2COOH$
   (butyric acid) (acetoacetic acid)
2. $CH_3CH_2CH_2CH_2COOH \rightarrow CH_3CH_2COCH_2COOH$
   (valeric acid) (3-ketovaleric acid)

In the case of a fatty acid with an odd number of carbon atoms in the chain acetoacetic acid is not formed (Equation 2).

A third type of experimentation which shows that β-oxidation takes place has been employed by Quastel and his associates.[385] They measured the amount of acetoacetic acid formed by slices of liver (guinea pig) following the addition of various fatty acids. Their results are given in Table LXXXII. With this sensitive method, results similar to those of Embden were obtained, although the fatty acids with an odd number of carbon atoms did give slight amounts of acetoacetic acid.

TABLE LXXXII

FORMATION OF ACETOACETIC ACID FROM FATTY ACIDS (FROM QUASTEL AND JOWETT[385])

FATTY ACID	NO. OF C ATOMS	QAC. (MG. ACETOACETIC ACID PER MG. OF TISSUE PER HOUR)
Acetate	2	0.38
Butyrate	4	3.06
Valerate	5	0.95
Hexonate	6	2.93
Heptanoate	7	0.80
Octanoate	8	2.22
Decanoate	10	0.81
Control	—	0.25

A fourth type of experimentation which has demonstrated a difference in the catabolism of the odd and the even carbon fatty acids is the study of the ability of various fatty acids to form glycogen in the liver. Deuel and his associates[379] have shown that the odd chain fatty acids, propionic, valeric, heptoic, and nonylic, aid in the formation of glycogen, but the even chain ones do not.

ω-Oxidation and Combined ω- and β-Oxidation.—Another type of oxidation is the ω-oxidation. Verkade and van der Lee[407] found that dicarboxylic acids are formed from certain fatty acids fed to human subjects. They explained their results by assuming that oxidation takes place at both ends of the chain, a combination of ω- and β-oxidation:

$$CH_3CH_2CH_2(CH_2)_nCH_2CH_2COOH \xrightarrow{\omega\text{-oxidation}} HOOCCH_2CH_2(CH_2)_nCH_2CH_2COOH$$
two sided β-oxidation
$$\rightarrow HOOC(CH_2)_nCOOH$$

The relative importance of ω-oxidation as contrasted with β-oxidation is not known. ω-oxidation does not give rise to ketone bodies but does give succinate. Therefore, this type of oxidation does not explain the production of ketone bodies during abnormal types of metabolism, but does explain fat transfer to carbohydrate, since succinate can be converted readily into glucose by animal tissues.

Desaturation.—The fourth type of oxidation of the fatty acid molecule is desaturation, or removal of hydrogen. Leathes and Raper[388] have summarized the evidence in support of the view that fats are transported from the storage deposits to the liver where the first step in their metabolism is a desaturation. The evidence for this metabolic change has been obtained by feeding rats cod liver oil (Leathes and Meyer-Wedell[387]), since on this diet, the fat in the liver has a higher iodine value than the ingested fat. Additional recent evidence has been supplied by Schoenheimer and his associates[402] using deuterium labeled fat. Their experiments show that saturation and desaturation of fatty acids occur constantly. It has been suggested that the process of desaturation is not primarily for complete oxidation but merely to make a fat liquid at the temperature of the body. Whatever the purpose may be, it is a form of oxidation.

Ketone Body Formation.—In the previous sections, the end products of the metabolism of the fatty acids with an even number of carbon atoms were given as follows: acetoacetic acid, acetone and β-hydroxybutyric acid. These substances, called ketone bodies, do not appear in the blood or urine under normal circumstances. However, under abnormal circumstances such as carbohydrate starvation or diabetes mellitus, large quantities of ketone bodies accumulate in the blood and urine. Under such abnormal conditions the carbohydrate supply is reduced and the products of incomplete combustion of fat appear. If carbohydrate is given to a starving subject, or if insulin is injected into a diabetic, the ketone bodies disappear. These facts illustrate that there is a direct or indirect connection between fat and carbohydrate metabolism.

Various questions arise as to the quantitative production of ketone bodies from fat, and the quantity of carbohydrate in the food, necessary to prevent ketone body formation. The older idea was that one molecule of fat gave rise to one molecule of a ketone by successive β-oxidation of the fatty acid. This process, supposedly, stopped at the ketone stage. These products were looked upon as waste products which disturbed the acid-base equilibrium of the blood and depleted the body of base in their excretion. In order to return the body to its normal state, all of the ketone bodies had to be excreted by the kidneys. Modern work has revised these concepts. Jowett and Quastel,[385] from their study of the formation of ketone bodies in liver slices, have shown that the higher fatty acids can give rise to more than one molecule of ketone. Deuel[19] and his associates, from feeding experiments, came to a similar conclusion. Blixenkrone-Møller,[373] using the perfused liver, and Stadie and his associates,[406] using liver slices, have calculated, from their experimental data, the molecular ratio of oxygen used for ketone formation and they have concluded that this ratio demonstrates that fat may be broken into multiple ketones:

$$\underset{\text{palmitic acid}}{C_{16}H_{32}O_2} + 5\ O_2 = 4\ \underset{\beta\text{-hydroxybutyric acid}}{C_4H_8O_3}$$

These numerous facts demonstrate that a multiple formation of ketones takes place from the higher fatty acids and that the older idea of only one molecule of ketone coming from a fatty acid molecule must be given up.

A second assumption formerly made was that ketone bodies are not used by the body but are entirely excreted. Perfusion experiments by Blixenkrone-Møller[373] have demonstrated that resting muscles are able to use ketone bodies and that stimulation accelerates this utilization. More recently, Stadie and his associates[406] have shown that minced muscle may use acetoacetic acid.

The question as to the amount of carbohydrate necessary to prevent ketone body formation was studied by Shaffer.[399] Taking into consideration the amount of sugar that may be derived from protein and fat, he proposed the following formula for calculating the carbohydrate necessary to prevent ketone body formation:

$$\text{Ratio} = \frac{2.4P + 3.43F}{3.2P + 0.57F + 5.56G}$$

In this formula P, F, and G represent grams of protein, fat and glucose metabolized.

The foregoing facts showing that a fatty acid molecule gives rise to more than one ketone body and that ketone bodies may be used by muscle, affect the theoretical implications in this calculation. Therefore, the ratio can only be used as a rough approximation of the relative amounts of food material ingested to prevent ketone body formation. Generally a ratio of 2:1 is taken for the minimal amount of carbohydrate needed for the prevention of ketone body formation.

The fact that the presence of adequate sugar in the liver diminishes the ketone body production may be explained in two ways: either the oxidation of carbohydrate aids in the oxidation of ketone bodies, a ketolytic process; or the metabolism of glucose inhibits the formation of these substances, an antiketogenic method. Mirsky and his associates[393] have presented considerable evidence to show that there is competition for substrates in the liver. When glucose is present, glucose is oxidized by preference; whereas if glucose is absent or low in concentration, then fat is used and ketone bodies are formed. Therefore, there is only an indirect connection between the oxidation of fats and carbohydrates. It might be said, however, that the process is one of antiketogenesis.

Ketone bodies are formed by the liver to meet the need of the muscles when carbohydrate supplies are low. Thus, they are useful metabolites and not waste products of fat metabolism.

THE CONTROL OF FAT METABOLISM

Although the control of fat metabolism is not as clearly defined as the regulation of carbohydrate metabolism, numerous factors, neural, endocrine and vitamin, have been described which affect fat metabolism.

Neural Control.—The only definite experimental evidence of neural control has come from a study of lesions in the region of the hypothalamus. Studies of the effects of such lesions have demonstrated that this part of the brain is concerned with fat metabolism. Smith,[405] by injection of chromic acid into

TABLE LXXXIII

Fat in body, per cent	58	16
Liver fat, per cent	24	36

the hypothalamus, produced an increase of over 100 per cent in the body weight of rats. This increase in weight was due to the accumulation of fat. Some of the analyses made by Foster and Benninghoven[383] on these animals are given in Table LXXXIII. It may be seen in this table that 58 per cent of the body weight of the experimental animal was fat in contrast to 16 per cent in the control animal. A similar increase in weight in the monkey has been described by Ranson and Ingram[395] and by Brooks[374] following hypothalamic lesions. Exact metabolic studies on these animals have not been made, especially as to their intake of food. The accumulation of fat may be secondary

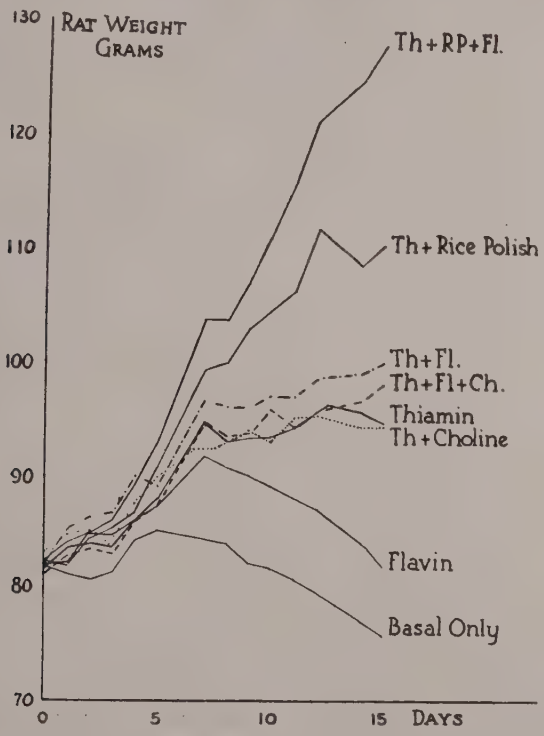

Fig. 297.—Effect of B vitamins on body weight. (From McHenry and Gavin: J. Biol. Chem. 125: 657, 1938.)

to some other change causing an increase of appetite or a decrease in metabolism. These experimental findings show clearly, however, that the hypothalamic region controls the deposition of fat.

There is no good evidence at the present time that peripheral nerves or the sympathetic system may mobilize fat.

Hormonal Control.—Numerous extracts from the endocrine glands affect fat metabolism either directly or indirectly. Insulin, by allowing carbohydrate to be stored in the liver, indirectly decreases fat metabolism and the produc-

tion of ketone bodies. Extracts from the anterior pituitary gland cause an increase of the ketone bodies in blood and urine, and an accumulation of fat in the liver (MacKay and Barnes;[391] Best and Campbell[372]). By using fat tagged with deuterium, Best and his associates[367] have shown that the fat which accumulates in the liver comes from fat depots. Therefore, this extract has the ability to mobilize fat from the storage regions.

The fact that fat accumulates in the liver of a depancreatized dog which has been fed insulin, suggests that there may be a fat-controlling hormone in the pancreas which has a direct action on fat metabolism. Dragstedt[380] has described such a hormone, prepared from the pancreas, that has the property of preventing these fatty livers. He has called this hormone "lipocaic," meaning the "fat-burning" hormone. Dragstedt has shown that, in its preparation lipocaic is freed of choline and lecithin and, therefore, has a separate action from these two compounds.

Vitamin and Dietary Control.—In addition to the lipocaic control of the fatty livers in experimental diabetes, choline has also been shown to possess the property of removing this fat. This discovery resulted from a series of observations: first, that the feeding of raw pancreas to the diabetic (Hershey and Soskin[384]) is effective; then that lecithin acts efficiently; and finally, that choline (Best and Huntsman[369, 370]) is the active component in this compound. A working hypothesis of the action of choline has been given by Best[360]). Choline is essential in the formation of phospholipid in the liver. In its absence, neutral fat accumulates and the presence of an excess of fat in the liver decreases the liver function. These findings are of interest in connection with fat transport, since they illustrate the importance of the production of phospholipid for the mobilization of fat from the liver to the tissues.

Diets low in protein also produce fatty livers which may be restored to normal by dosage with casein (Best and Huntsman;[371] Channon[376]). The activity of casein is much less that of choline, for 1 gram of casein is required to equal the activity caused by 5 to 8 mg. of choline. The action of casein in this respect may be due to the presence of one or more active amino acids. Methionine has been shown to decrease the fat in fatty livers and tyrosine has a slight action. Cystine, on the other hand, produces fatty livers. Therefore, the final result of any ingested protein would depend on the relative amounts of the amino acids having the power to deposit or to remove fat from the liver. The actual chemical mechanisms involved are not known.

The Effect of Other Vitamins on Fat Metabolism.—McHenry and Gavin[392] have shown that a diet without choline but containing vitamin B_1 will cause large amounts of fat to accumulate in the liver. This increase in fat was greater than could be accounted for by the fat in the diet. It was demonstrated also that vitamin B_1 with riboflavin and rice polishing gives a greater effect than any one of these constituents. These results are illustrated in Fig. 297.

Various unsaturated fatty acids are essential for some of the functions of the body. These substances will be discussed in the chapter on Vitamins (Chapter LVI).

CHAPTER LVI

VITAMINS

A diet may be quantitatively adequate with regard to calories, essential amino acids, and inorganic elements, but may be incomplete for maintenance and growth unless it contains accessory food factors, the vitamins. These substances may be defined as essential constituents of the diet, organic in nature, incapable of synthesis by the body and effective in playing a part in the maintenance of the normal functioning of tissues in amounts minute by comparison with those of the foodstuffs which supply structural material and energy (Drummond[409]).

The reason that a discussion of vitamins is included in a textbook of physiology is that these substances play a prominent role in the control of metabolism similar to the hormonal control. In fact, they can be looked upon as hormones derived from plant sources. Their function, however, is not as spectacular as that of animal hormones whose activity can be measured in terms of minutes or hours. The absence of a vitamin may be revealed only after days or weeks of feeding a deficient diet; however, after that time, characteristic pathological symptoms show themselves. The delay in the appearance of symptoms is due in part to the fact that the animal body is able to store a small amount of the needed vitamins.

The lack of certain vitamins produces characteristic diseases of which beriberi, scurvy, and pellagra are outstanding examples. Scurvy, according to Garrison,[440] afflicted 75 per cent of the men of Lord Anson's fleet in 1740. Through the introduction of lime juice in 1795 scurvy disappeared from the British Navy, and, by 1797, not a single case was discovered. This was the first triumph for vitamins. Beriberi has claimed hundreds of victims and is still prevalent in eastern countries where the diet is chiefly rice. Sebrell[471] calculates that there are 100,000 cases of pellagra in this country. It is obvious that a knowledge of vitamins is essential, not only from a physiological view, but also from a medical and a public health standpoint.

One of the difficulties of studying vitamins is that different species do not require the same vitamins, and even when they do, different amounts are needed by the various ones. For example, only man, other primates, and guinea pigs do not have the ability to make ascorbic acid (vitamin C). Another difficulty has been that the terminology employed has been changed frequently with the advances in this field. Fortunately, because some of the vitamins are recognized as chemical compounds, the older terms are now being changed to their chemical names, thus giving definite meaning to the terminology.

Vitamins bridge the gap from the plant to the animal kingdom, for they are produced only in plants and are needed by animal tissues for carrying out fundamental metabolic processes. The first clear evidence that growth of animals is dependent not only on proteins, fats, carbohydrates, and salts but also on accessory factors was obtained from the experiments of Hopkins[453] (Fig. 298). Since then tremendous advances have been made in the field. The most outstanding achievement in recent years has been the discovery that certain

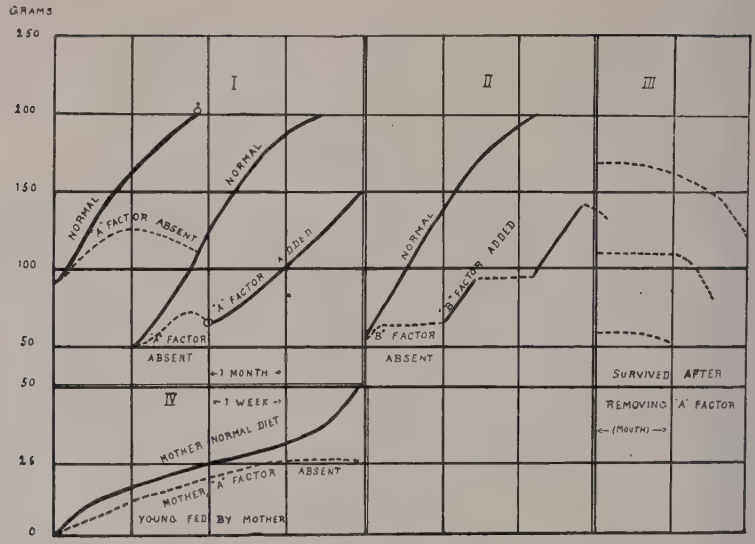

Fig. 298.—Curves of growth of rats as influenced by the accessory food factors. I. The effect of the "A" (fat-soluble) factor. Note that the curve does not immediately descend after removal of this factor from the diet. II. The effect of the "B" (water-soluble) factor. Note that growth ceases immediately after it is withdrawn. III. The time during which animals survive after removal of the "A" factor at different ages, the uppermost curve being that obtained for rats that were nearly mature before the factor was removed from the diet and the lower ones for less mature animals. IV. The continuous curve is for young fed by mothers receiving "A" factor in their diets; the broken-line curve is for young fed by mothers receiving none of this factor. (From Hopkins and Chick.)

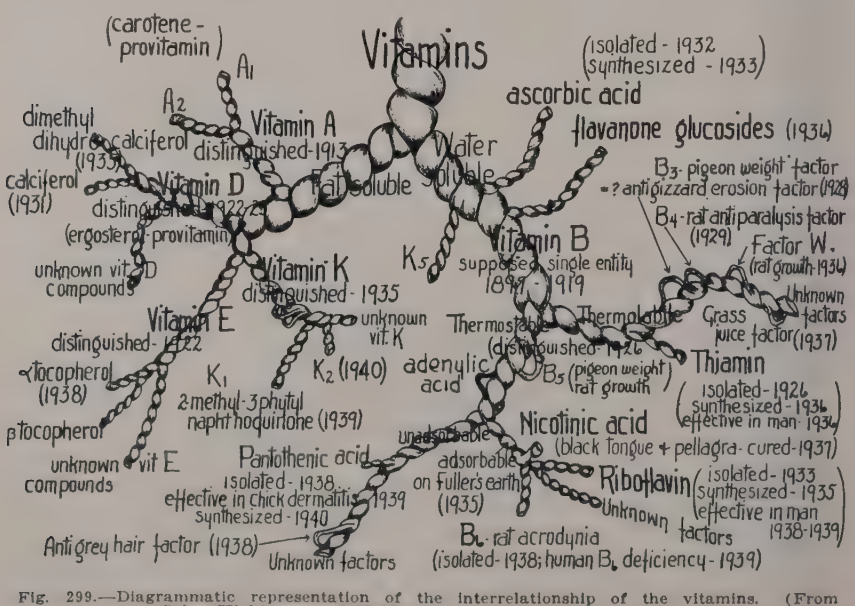

Fig. 299.—Diagrammatic representation of the interrelationship of the vitamins. (From Spies, Hightower and Hubbard: J. A. M. A. 115: 292, 1940.)

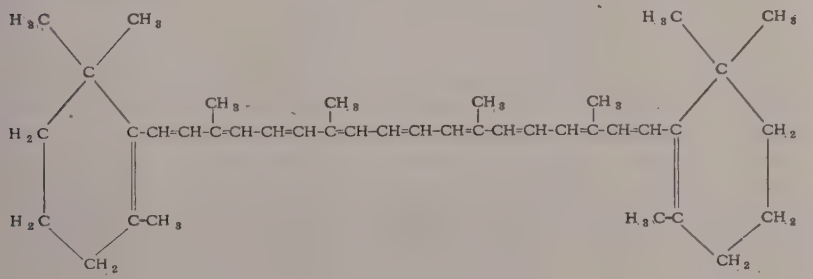
vitamins are concerned with coenzyme activity. This discovery has come through two independent developments, the study of cellular respiratory mechanisms as an enzymatic process and the study of vitamin deficiencies. Although all the manifestations of vitamin deficiency cannot be explained on the basis of cellular respiratory mechanisms, a start has been made and future advances may be anticipated along these lines.

Many vitamins have been described. On the basis of their biological activity, they are divided into several groups which were designated originally by the letters of the alphabet. They will be discussed in the order of the letters. Fig. 299 gives a diagrammatic representation of the interrelationship of the vitamins (Spies, Hightower and Hubbard[477]).

VITAMIN A

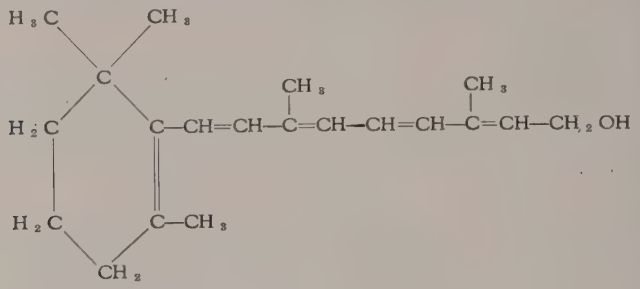
In the same volume of the *Journal of Biological Chemistry* (1913), McCollum and Davis[458] and Osborne and Mendel[465] independently reported the necessity of adding butter to a synthetic diet in order to obtain adequate growth in rats. Later, Osborne and Mendel noticed that animals receiving insufficient amounts of butter developed eye lesions. This pathological change in the eyes, known as xerophthalmia, is characterized by a drying of the cornea and conjunctiva with ulceration and degeneration. Cod liver oil has the property of preventing these lesions (Osborne and Mendel). This oil also prevents rickets, and it was once thought that a single vitamin controlled both conditions. McCollum and his associates[459] were able to show, however, that there are two distinct vitamins. Oxidation of cod liver oil destroys the power of this substance to cure xerophthalmia but does not remove the factor which prevents rickets (vitamin D). Therefore, vitamins A and D are separate substances.

Chemistry of Vitamin A.—Steenbock and his associates[472, 473] demonstrated a relationship between the presence of a yellow pigment (carotene) in plants and vitamin A. They observed that foods, such as carrots, yellow sweet potatoes, and yellow corn, are rich sources of vitamin A, while white corn is deficient. Although the yellow pigment is associated with vitamin A activity, there are colorless or almost colorless materials, such as cod liver oil, that have similar potency. Therefore, carotene is not vitamin A. The exact relationship between carotene and vitamin A was demonstrated by von Euler and his associates.[435] They showed that the administration of as little as 0.005 mg. of purified carotene per rat per day enabled the animals to grow normally. The obvious conclusion is that carotene is a precursor of vitamin A and that it may be readily changed into this vitamin in the animal body. There are several known isomers of carotene, α, β, and γ compounds, all of which may be converted into vitamin A. The formula for β-carotene is:



Cryptoxanthin, a compound closely related to carotene, also has precursor activity.

Vitamin A has been isolated in crystalline form by Holmes and Corbet.[452] It is an unsaturated alcohol and has the following formula:



The crystalline material has a biological potency of about 3,000,000 international units per gram. A chemical difference has been discovered between the vitamin A in the livers of salt and fresh water fishes (Gillam et al.[442]). The vitamin A described above is called A_1 and comes from salt water fish. A_2, from livers of fresh water fish, has an additional double bond. There may be other closely related compounds which have vitamin A activity.

The precursors of vitamin A are absorbed in the intestine from the ingested food material. They are carried to the liver where they are broken down into this vitamin. However, not all of the precursors are broken down immediately and thus the liver may act as a storehouse for vitamin A. There seem to be considerable differences between species as to their ability to utilize the precursors of vitamin A. Even in a single species there is considerable variation in utilization of the precursors when they are supplied in different foodstuffs.

A unit of vitamin A has been defined as the biological activity of 0.6γ of pure β-carotene. It is estimated that from 3,000-6,000 units are required for an adult per day. In plant foods, vitamin A is present only as a precursor, but in milk and butter both precursor and vitamin A are present. In fish oils, the active material is all in the form of vitamin A. Natural sources of vitamin A are yellow corn, spinach, carrots, prunes, butter, cheese, eggs, liver, and fish liver oils (Levine[413]).

Vitamin A Function.—The characteristic features of vitamin A deficiency in man have been summarized by Eusterman and Wilbur.[436] The absence of this vitamin in the diet produces, in addition to the failure of growth, two types of eye changes: night blindness (nyctalopia) and xerophthalmia. Night blindness is defined as the inability to adapt the faculty of vision to very faint illumination and is associated with changes in the visual purple (see Chapter XXIII). Fridericia and Holm[439] have shown that there is a delay in the regeneration of the visual purple in rats suffering from vitamin A deficiency. Wald[484] has demonstrated that the visual purple system uses vitamin A and is dependent on the presence of this vitamin in the diet for its replacement.

The relationship between dark adaptation and vitamin A has led to the use of an instrument, the biophotometer, for the study of this reaction. The test is based on the

changes occurring in the eyes of an individual when he is exposed to a brilliant light and later subjected to point illumination. Numerous types of this instrument have been devised (Hecht[448]). In applying the biophotometer test to a large number of individuals, there are definite limitations. For example, there is a learning factor which may render the test inadequate for mild degrees of vitamin A deficiency. Moreover, there is a marked variation in normal individuals which makes difficult the establishment of a normal threshold value of dark adaptation. In a study of four normal men on a diet low in vitamin A, Hecht and Mandelbaum[449] observed with a biophotometer that both cone and rod functions are disturbed by the lack of vitamin A and that they are restored by the addition of this vitamin to the diet.

Another eye lesion is xerophthalmia, which, in man, is characterized by drying of the cornea with corneal softening and secondary infection. In addition to the eye lesions, there are cutaneous changes consisting of a dry, scaly, shriveled condition of the skin. Changes in the bronchial epithelium have been described. In fact, vitamin A deficiency affects all the mucous membranes and the skin. The infections that develop are probably secondary. The "anti-infective" function of vitamin A claimed by some investigators has not been clearly established.

THE VITAMIN B COMPLEX

At one time, it was supposed that a single vitamin, B, had the property of preventing polyneuritis in pigeons and beriberi in man and of promoting growth in young animals. This vitamin, however, has been subdivided into numerous fairly distinct factors. Table LXXXIV gives a summary of these substances as they are at present designated.

TABLE LXXXIV

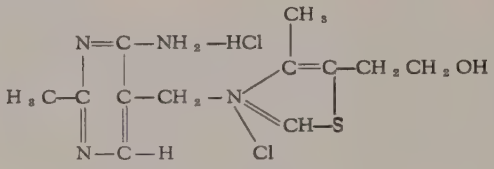
THE VITAMIN B COMPLEX

ALPHABETICAL NAME	CHEMICAL NAME	FUNCTION
B_1	Thiamin chloride	Antineuritic factor
B_2	Riboflavin	Preventative of skin lesions
B_3	----	Necessity for growth of pigeons
B_4	----	Preventative of paralysis in rats and chicks
B_5	----	Necessity for growth of pigeons
B_6	Pyridoxine	Antidermatitis factor for rats
P-P (Pellagra Preventive)	Nicotinic Acid	Preventative of skin lesions
Factor W	----	Growth factor for rats
----	Pantothenic Acid	Preventative of dermatitis in chicks

Vitamin B_1.—The first thorough experimental work on this accessory food factor was carried out by Eijkman[429] who noticed that fowls fed on polished rice develop a typical polyneuritis and exhibit symptoms similar to those characteristic of beriberi in human beings. Eijkman demonstrated that the addition to the diet of the material removed by the polishing cures these animals. Emmett and Luros[432] showed that there are two factors involved in the unmilled rice, the antineuritic vitamin (pigeons) which is destroyed by heating and the growth promoting factor (rats) which is heat-resistant. Goldberger and his associates[443] were able to demonstrate the dual nature of this vitamin by making an alcoholic extract of corn meal. Such an extract has the power of curing polyneuritis but does not contain the growth factor. Autoclaved yeasts which have the property of curing dermatitis, when added to the alcoholic extract, cure the polyneuritis and promote growth. These experiments divided vitamin B into two components; one which has the power of curing and pre-

venting polyneuritis and the other which prevents and cures dermatitis and allows growth to take place normally. Further subdivision has taken place. Vitamin B_1, at the present time, may be defined as a water-soluble, heat labile vitamin having the property of preventing avian polyneuritis and human beriberi.

The Chemical Nature of Vitamin B_1.—Williams and his associates[487] have obtained this vitamin in pure crystalline form and have given the following formula for its structure:



Vitamin B_1 (thiamin hydrochloride)

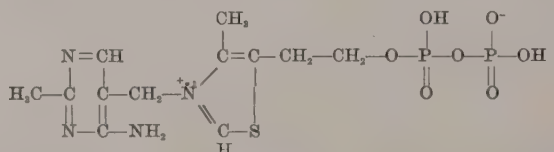
A clinical trial of the crystalline material has demonstrated its antineuritic activity.

Vitamin B_1 Function.—In human beings, deficiency of this essential food factor results in beriberi, a disease characterized by peripheral neuritis. There are two forms of this disorder: the wet and the dry. In the wet type, there is extensive edema of the extremities while the dry form is characterized by wasting and paralysis of the limbs. The gastrointestinal tract is also affected, for Cowgill and his associates[427] have shown in dogs that there is marked gastric atony in severe cases of deficiency of this vitamin.

Outstanding work in this field was the recognition that vitamin B_1 enters into an enzymatic reaction, converting a keto acid into an aldehyde, a decarboxylation:

$$CH_3COCOOH \rightarrow CH_3CHO + CO_2$$

As early as 1911, Neuberg and Hildesheimer[463] discovered that yeast contains an enzyme, carboxylase, which converts keto acids to aldehyde. In 1932 Anhaugen[421] demonstrated that carboxylase requires a coenzyme for its activity. This coenzyme was shown by Lohmann and Schuster[49] to be the pyrophosphoric acid ester of vitamin B_1.



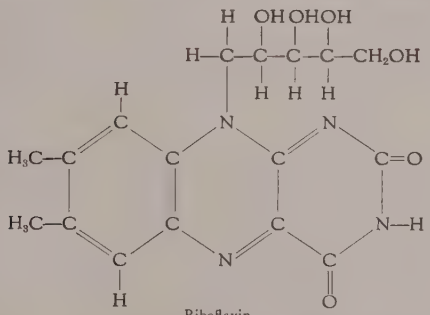
Cocarboxylase

Before this discovery, Peters and his associates[466] had studied the effect of vitamin B_1 on the metabolism of brain tissue of pigeons suffering from the lack of this vitamin. They had observed two effects: vitamin B_1 increases the oxygen uptake and decreases the formation of pyruvate by such brain tissue. Pyruvate accumulates in the blood of pigeons and rats suffering from vitamin B_1 deficiency (Thompson and Johnson[481]), and the amount present is increased by exercise in these vitamin B_1 deficient animals. These facts demonstrate that vitamin B_1 has the same activity in brain tissue as in yeast; namely, it aids in the oxidation of pyruvate, and in the absence of this vitamin pyruvate accumu-

lates. It has been demonstrated also that mammalian tissue has the ability of phosphorylating vitamin B_1 to form the coenzyme, cocarboxylase.

Cowgill[418] has recently reviewed the human requirements for vitamin B_1, and found that the amount needed varies with the size of the individual. He advises 280 international units for a man weighing 70 kg. and 550 units for a man weighing 90 kilograms. The international unit is defined as the vitamin B_1 activity of 3 micrograms of crystalline vitamin B_1. The natural sources of vitamin B_1 are wheat germ, bran, tomatoes, prunes, egg yolk, kidneys, oysters, yeast, and nuts (Levine[413]).

Riboflavin (Vitamin B_2).—It had long been recognized that the growth of rats requires a component formerly called B_2. Kuhn and his associates[445] noticed that the ability of a material to promote growth in rats is associated with a yellow color and green fluorescence which are characteristic of a class of compounds called flavins. Flavins have been isolated from milk, liver, heart, skeletal muscles, yeast and egg white. Following the synthetic production of flavins, it was demonstrated that their synthetic activity was similar to that of the naturally occurring product. The structural formula for riboflavin is:



Riboflavin

This substance does not cure black tongue in dogs or pellagra in man. There has been recognized for years a "pellagra sine pellagra" characterized by erosions at the angles of the mouth, and seborrhea about the nose which occurs in patients suffering with pellagra (see page 824). This led early workers to postulate that multiple dietary factors may be involved in this clinical condition. Sebrell and Butler[470] have recently shown that these lesions appear in human cases on diets low in riboflavin and are cured or prevented by giving the patient synthetic riboflavin but not nicotinic acid, which is the pellagra-preventive vitamin. The importance of riboflavin in cellular respiration is discussed in Chapter XLVIII. It is estimated that 2 to 3 mg. daily are necessary. The common sources of vitamin B_2 (Levine[413]) are spinach, carrots, lettuce, pears, bananas, dried prunes, milk, eggs, liver, beef, and brewer's yeast.

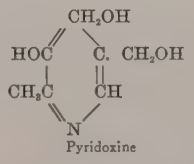
Vitamin B_3.—This factor may be defined as a substance required for full weight restoration in the pigeon on a diet which, in addition to vitamins B_1 and B_5, includes an adequate supply of basal dietary constituents, such as salts and proteins (Carter and O'Brien[425]). A pigeon receiving large doses of vitamin B_1 attains only about 80 per cent of its normal weight. If, however, an extract of liver is added to the diet, it grows normally. This extract has been subdivided into two effective factors by Carter and O'Brien.[425] The first factor is

adsorbed in fuller's earth and carries with it a flavin, while the other is present in the filtrate after treatment with fuller's earth. The adsorbed fraction has slight growth promoting activity, but the maximum effect is obtained only when both factors are combined in the diet. This vitamin is found in whole wheat, yeast, and liver.

Vitamin B_4.—Reader and her associates[467] have described two heat- and alkali-labile substances in water extracts of yeast. The one factor is B_1, already described, while the other is termed B_4. Reader gives the following symptoms as typical of vitamin B_4 deficiency. In addition to retarded growth, the rats show spastic gait, muscular weakness, and loss of coordination. A crystalline compound has been prepared that has vitamin B_4 activity. This compound has been identified as adenine which in itself has no power to protect rats from vitamin B_4 deficiency. The vitamin is probably carried with the adenine as an impurity. The natural sources of this substance are whole wheat, lettuce, milk, liver, and yeast.

Vitamin B_5.—Carter, Kinnesley and Peters[424] have described a factor, which is not identical with B_2, B_3, or B_4, but is necessary for the nutrition of the pigeon and have termed it vitamin B_5. They claim that three factors are necessary for nutrition in the pigeon, B_1, B_3, and B_5 while B_1, B_2, and B_4 are needed by the rat. Such conclusions illustrate the present complexity of the vitamin problem. It may be that different species require different nutritional factors of this type.

Pyridoxine (B_6).—In their studies on pellagra, Goldberger and Lillie[444] reported that a disease in rats characterized by dermatitis could be produced by the same deficient diets as those which produced black tongue in dogs and pellagra in man. Later work demonstrated that the lesions produced are not caused by a deficiency of nicotinic acid nor of riboflavin but are due to a separate substance (György[446]). This compound has been isolated (György[447]) and the following formula given:



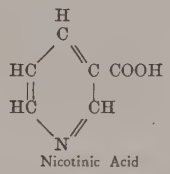
Pyridoxine

Rats are cured of dermatitis when fed 5 to 10 mg. of the hydrochloride of this material per day. Spies and his associates[476] have demonstrated that this compound has the property of curing a certain type of muscular weakness in man.

Factor W.—Elvehjem, Koehn and Oleson[432] have described another factor essential for the growth of rats kept on a deficient vitamin B diet to which adequate amounts of B_1, B_2, and B_4 were added. They concluded that this additional factor is necessary for the growth of rats.

Nicotinic Acid (Pellagra-Preventive).—Goldberger and his associates[443] showed that pellagra is a deficiency disease in man and that black tongue in dogs is analogous to pellagra in man. These two conditions are produced or cured by the same diets. The symptoms are similar, in that in both diseases there is stomatitis, diarrhea, secondary anemia, and dermatitis of the scrotum. The factor necessary for the cure of these conditions was called the pellagra-

preventive (P-P) factor by Goldberger, and was included in the old vitamin B_2 group. Elvehjem[431] showed that the compound which has the property of curing black tongue in dogs was nicotinic acid or its amide. Spies[475] and Fonts and his associates[438] applied this finding to patients and were able to cure human cases with the pure compound. The structural formula for nicotinic acid is:



Nicotinic Acid

The importance of nicotinic acid in cellular respiration was discussed in Chapter XLVIII in which it was pointed out that this substance enters into the pyridine nucleotides that form the coenzyme systems for oxidation of numerous substrates. The amount of this coenzyme is reduced in vitamin deficient animals.

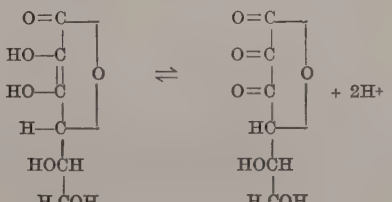
The requirement of nicotinic acid for normal man is from 10 to 25 mg. per day. Spies advises half a gram daily for curing pellagra.

Pantothenic Acid.—Williams[486] described a substance that accelerates the growth of yeast. Its activity is very great, for only 5 parts in 10 billion parts of culture medium are needed to produce an effect. In a later paper,[487] he and his associates showed that the calcium salt of this substance has the empirical formula $(C_8H_{14}O_5N)_2$ Ca. This substance turns out to be identical with a vitamin necessary for the cure of chick dermatitis (Woolley, Waisman and Elvehjem[488]).

VITAMIN C

Most of our knowledge concerning vitamin C has come from clinical observation because many animals do not require this factor. Guinea pigs are, however, very susceptible to its absence. When these rodents are fed on a diet of grain, their joints become swollen and tender, causing the animal to lie in such a position as to minimize the pain. The teeth become loose and can be pulled out readily. Postmortem examination reveals hemorrhages in the tissues of the limbs and alimentary canal. Similar symptoms and pathological changes are seen in scurvy in man.

Chemistry of Vitamin C.—It has been known for a long time that fruit juices have the property of preventing scurvy. Working independently, Waugh and King[485] and Svirbely and Szent-Györgyi[479] discovered that it is ascorbic acid which has antiscorbutic activity. Szent-Györgyi[480] had previously isolated this compound from the adrenal cortex and from plants. The following formulas have been given the l-form and its oxidized product:



l-Ascorbic acid Dehydroascorbic acid

Although ascorbic acid is a strong reducing agent and may be rapidly oxidized in vitro, it is relatively stable in the animal body. On account of its reducing property, many attempts have been made to find a definite place for ascorbic acid as a hydrogen carrier in tissue respiration, but as yet these have been unsuccessful.

Stotz and his associates[478] have demonstrated that ascorbic acid increases the oxygen consumption of guinea pig liver. Schultze, Stotz, and King[469] showed that the protein sulfhydryl groups have the power of reducing dehydroascorbic acid to ascorbic acid very readily. Gemmill and Hellerman[441] have shown that ascorbic acid has the ability to reactivate the muscle glycolytic systems, inactivated by oxidizing agents. It is surprising that such an active agent as ascorbic acid has not found a definite place in cellular respiration.

The l-form is the active substance, for the d-isomer has no activity. The international unit is, at the present time, 0.05 mg. of l-ascorbic acid. The daily requirement is considered to be from 30 to 60 mg. for the prevention of scurvy (Abt and Farmer). The natural sources for this vitamin are fresh corn, spinach, peas, lemons, oranges, strawberries, apples, milk, and liver (Levine[413]).

VITAMIN D

This vitamin controls the deposition of calcium and phosphorus in bones and teeth. In its absence the disease known as rickets (rachitis) develops. Mellanby[462] showed that cod liver oil, butter, and fat have a marked antirachitic action. Since these substances also contain vitamin A it was first thought that this vitamin possesses the antirachitic action. However, when McCollum and his associates[459] found that cod liver oil, after oxidation, no longer shows typical vitamin A activity but retains its antirachitic power it was concluded that the two effects depend on two separate factors.

Fig. 300.

Fig. 301.

Fig. 300.—Photograph of two puppies after being fed for eighteen weeks after weaning on the same diet, deficient in vitamins A and D. Puppy 1 (left) was the offspring of a mother fed during pregnancy and lactation on a diet rich in vitamins A and D and containing bread as the cereal, whereas the mother of puppy 2 (right) was fed on a diet deficient in these vitamins and having oatmeal as the cereal. It will be noted that puppy 1 shows little sign of rickets, while puppy 2 has developed severe rickets. (Reproduced by permission of Controller of H. M. Stationary Office from Med. Res. Council Report No. 167.)

Fig. 301.—Rickets following a diet of 175 ml. of whole milk, white bread ad lib., and 10 ml. of linseed oil per day. Time of experiment, 5½ months. Increase in weight during period of experiment 2,670 Gm. (Reproduced by permission of Controller of H. M. Stationery Office from Med. Res. Council Report No. 167.)

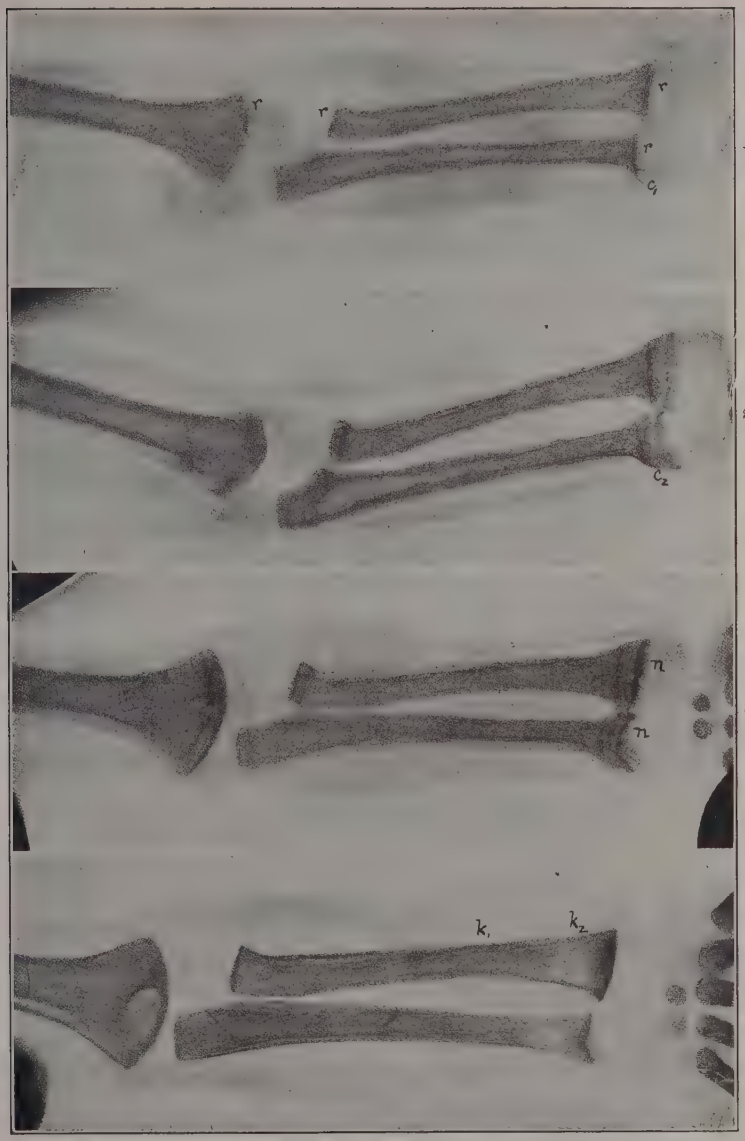


Fig. 302.—X-ray photographs illustrating severe rickets in a child of ten months and recovery after treatment with cod liver oil. (Reproduced by permission of Controller of H. M. Stationery Office from Med. Res. Council Report No. 167.)

1. March 10, 1922. Florid rickets, osteoperosis. Structure of bones coarse, metaphyseal margins (r) frayed. Distal end of ulna slightly cupped, uncalcified osteoid zone at C_1.

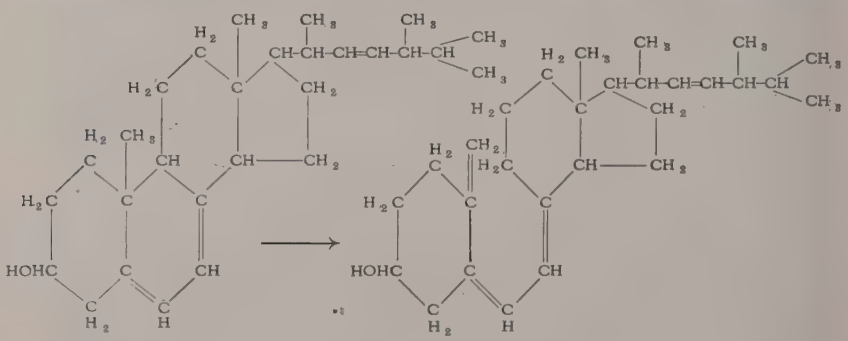
2. April 4, 1922. Healing in progress after twenty-seven days' treatment. Calcium depositing along the shafts, at metaphyseal margins and at C_2.

3. April 11, 1922. Rapid progress. Dense calcification at n; increase in periosteal calcification; calcification of center of ossification at distal end of humerus.

4. June 15, 1922. After three months' treatment. Contour of shafts nearly normal, bone finely meshed. Fine homogeneous new bone (k_2) distinguishable from k_1, formed before onset of rickets.

The diagnosis of rickets rests on the following: Clinical examination shows that the bones are deformed (Figs. 300 and 301); there is beading of the costochondral junctions and enlargement of the epiphyses. It is difficult, however, from clinical examination alone to decide whether the process is an active one, and in its earliest stages the disease defies ordinary methods of examination. Therefore the radiographic method must be employed. The photographs reproduced in Fig. 302 show different stages of rickets in the dog. Histological examination demonstrates the presence of uncalcified osteoid tissue which accumulates at the epiphyses in amounts varying with the intensity and duration of the disease.

Chemistry of Vitamin D.—Huldschinsky[454] in 1919, discovered that infantile rickets can be cured by exposure to ultraviolet radiation. Later, Hess and Unger[450] found that sunlight has the same curative effect. The next step in advance was that of Hess and Weinstock[451] who demonstrated definitely that food deficient in vitamin D develops anti-rachitic properties when it is exposed to ultraviolet light. It was thought at first that cholesterol is the material involved in the change. Rosenheim and Webster[468] demonstrated, however, that the provitamin activity is possessed by an impurity carried down with the cholesterol. This substance was identified as ergosterol. Rosenheim and Webster found that as little as 0.0001 mg. of irradiated ergosterol per day prevents rickets in rats. The next step in the development of this subject was the isolation of a crystalline antirachitic substance from solutions of irradiated ergosterol. Askew and his associates,[420] using distillation in a high vacuum, obtained "calciferol" which represents vitamin D in a high state of purity. The



ergosterol

calciferol (vitamin D)
(Windaus)

chemical changes which take place in the molecule on irradiation include a rupture of the central ring of the phenanthrene nucleus and a formation of a methylene group at C_{18} in place of the original methyl group.

Several substances may act as provitamins which, on radiation, develop vitamin D activity. In fact, ten forms of vitamin D are known, but only two are of practical importance: the activated ergosterol of plant origin (calciferol) and the activated 7-dehydrocholesterol of animal origin. The experimental activation of a cholesterol of animal origin explains the curative effect of sunlight in human cases of rickets.

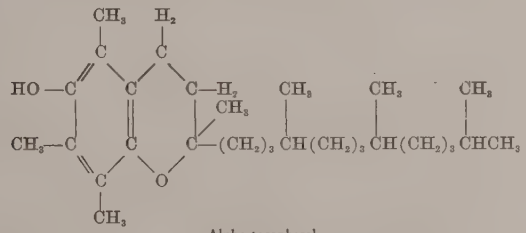
VITAMIN E

Proof of the existence of this vitamin has been more difficult to obtain than in the case of vitamins A or D. It was particularly from the work of Mattill and Conklin[461] and of Evans[433] that its existence was made probable. It was found that although rats fed on a milk diet do not breed normally, their reproductive functions are restored when lettuce, wheat germ, or yeast is added.

In the female rat, vitamin E deficiency leads to interference with the nutrition of the fetus so that it atrophies and is absorbed. If food containing this vitamin is given from the fifth to the nineteenth day after mating, the pregnancy will proceed to a successful issue, even though the diet preceding this period was deficient. In male animals, continued absence of vitamin E leads to incurable atrophy of the germinal epithelium of the testes.

Following the discovery of this vitamin, it was successfully applied to the cure of abortion in human cases.

Chemistry of Vitamin E.—This vitamin is unaffected by heat, light, acids, and alkalies. It occurs in the nonsaponifiable fraction of wheat germ oil. Evans, Evans, and Emerson[433] have isolated an alcohol which possesses vitamin E properties. Vitamin E has been purified and its structure established. It is an alpha-tocopherol and has the following structure (Karrn et al.;[455] Fernholz;[437] Smith et al.[474]):



Alpha-tocopherol

The natural sources of this vitamin are cereals, lettuce, bananas, milk, eggs, and muscles.

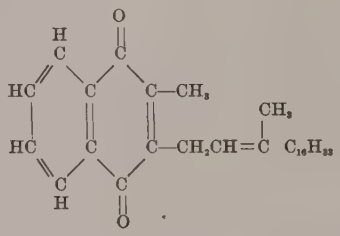
ESSENTIAL FATTY ACIDS

Burr and his associates[422, 423] have demonstrated the importance of some of the unsaturated fatty acids in nutrition. Feeding rats a purified diet of casein, sucrose, salt mixture, and vitamins A, D, and E, they discovered that these animals did not gain their full weight and developed a scaly condition of the skin, especially of the tail. This is cured and normal growth attained when small amounts of linoleic acid are added to the diet. Evans and Lepkovsky[434] have confirmed the observations of Burr that the essential substances are unsaturated fatty acids. Apparently, the animal body is unable to desaturate fatty acids to form these essential unsaturated acids or to make them synthetically.

VITAMIN K

The term vitamin K was proposed by Dam[428] to describe the substance (Koagulations Vitamin) necessary to prevent a hemorrhagic disease in chicks. This disease in chicks is characterized by a delayed clotting time and the ap-

pearance of hemorrhage. The delayed clotting time is associated with a low prothrombin content. The vitamin is a fat-soluble nonsterol portion of an ether extract of alfalfa. This vitamin has been prepared in pure form. The formula given to this vitamin is:



A detailed description of this vitamin and its use in blood coagulation studies is given in Chapter XXVIII.

CHAPTER LVII

NUTRITION: FOOD REQUIREMENTS AND INORGANIC SALTS

Burnet and Aykroyd[491] have described nutrition as an economic, agricultural, industrial and commercial problem, as well as a problem of physiology. Psychology may be added to the list since the sensation of taste and certain conditioned responses (see Chapters XXVI and XX) play important roles in nutrition. For the student of human physiology the subject of nutrition may be limited to a study of the nutritive requirements of man. These requirements are those of protein, carbohydrate, fat, calories, minerals, and vitamins. Nutrition, therefore, includes a study of the energy metabolism of man, because it is through such studies that the caloric requirement is determined. Thus such problems as the specific dynamic action of foodstuffs, the metabolism during exercise and the reaction of the metabolism of man to external temperature are parts of the subject matter of nutrition. In fact, this section (Part V) of the book is called "Metabolism and Nutrition." Two subjects which have not been discussed in the preceding chapters, namely, the caloric requirement of man and the need of inorganic ions, may conveniently be made the subject of a separate chapter.

Food Requirements

The latest study of the theoretical food requirements of man has been made by a Commission appointed by the Health Committee of the League of Nations.[491] The conclusions reached by this Committee are presented below:

1. **Caloric Requirements.**—Twenty-four hundred Calories per day are considered adequate for an adult living in a temperate climate and not engaged in manual work. To this basic requirement the following supplements should be added for muscular activity:

Light work:	50 Calories per hour of work.
Moderate work:	50-100 Calories per hour of work.
Hard work:	100-200 Calories per hour of work.
Very hard work:	200 Calories and upwards per hour of work.

The energy requirements of children and mothers are indicated in Table LXXXV.

TABLE LXXXV

AGE (YEARS)	COEFFICIENT OF NORMAL REQUIREMENT	CALORIES
1-2	0.2	720
2-3	0.4	960
3-5	0.5	1200
5-7	0.6	1440
7-9	0.7	1680
9-11	0.8	1920
11-12	0.9	2160
12 and upwards	1.0	2400
Women:		
Pregnant	1.0	2400
Nursing	1.25	3000

2. **Protein Requirements.**—The daily protein intake for all adults should not fall below one gram per kilogram of body weight. The protein should be

derived from a variety of sources and part of the protein should be of animal origin. During pregnancy and lactation some animal protein is essential, and in the growth period it should form a large proportion of the total protein. The required amounts are indicated in Table LXXXVI.

3. **Fat Requirements.**—Fat must be a constituent of a normal diet, but the data at present do not suffice to permit a precise statement of the quantity required.

TABLE LXXXVI

AGE (YEARS)	GRAMS OF PROTEIN PER KILOGRAM BODY WEIGHT
1-3	3.5
3-5	3.0
5-15	2.5
15-17	2.0
17-21	1.5
21 and upward	1.0
Women:	
Pregnant	2.0
Nursing	2.0

4. **Mineral and Vitamin Requirements.**—The Commission recognized the fact that the deficiencies of modern diets are usually in the protective rather than in the strictly energy-bearing foods. Among the former are, first and most important, milk and milk products, eggs and glandular tissues, then, green leaf vegetables, fruits, fat, fish, and meat. Among the energy-bearing foods of little or no protective power are sugar, milled cereals and certain fats. Refined sugar is entirely devoid of minerals and vitamins. The increasing habit of consuming large amounts of sugar tends to lessen the quantity of protective foods in the diet and is to be regarded with concern.

5. **Requirements of Pregnancy and Lactation.**—The Commission also attempted to define the quantity of protective foods necessary for perfect nutrition in terms of the requirements of the pregnant or nursing woman. She should be regarded as the member of the population needing the greatest "protection" in order to ensure adequate physical endowment for the child at birth and optimum nutrition during infancy. From a study of specimen diets, the Commission drew up the accompanying table (Table LXXXVII) which contains what is considered adequate for a nursing or pregnant woman.

This Commission also drew up the following general recommendations:

A. It is a general principle that a varied diet tends to safety, provided it contains a sufficiency of the protective types of food materials.

B. White flour in the process of milling is deprived of important nutritive elements.

C. The consumption of an excessive amount of sugar is to be condemned, and in this case partial replacement by potatoes is urged.

D. Milk should form a conspicuous element in the diet at all ages.

E. Fresh vegetables and fruit should always be constituents of the normal mixed diet.

F. Extra vitamin D, either as cod liver oil or as irradiated products, should be given whenever sunshine is not abundant, especially in the period of growth and during pregnancy.

The question now arises as to the actual quantities of these foodstuffs taken by the average person. The majority of people in civilized countries obtain sufficient food for energy purposes and adequate protein. Information concerning food consumption has been obtained by making a house-to-house study of certain districts. For example, Cathcart and Murray[492] investigated the diets of 154 families of St. Andrews, Scotland. They found that individual members of these families were ingesting 83.8 grams of protein, 118.6 grams of fat, and 410.7 grams of carbohydrate a day. The energy value of this diet was 3,119 Calories. According to the standards set by the Commission of the League of Nations such a diet is adequate as regards calories and protein. Unfortunately, similar studies were not made on the vitamin and mineral contents of the food of this group.

TABLE LXXXVII

DIETARY SCHEDULE FOR THE PREGNANT AND NURSING WOMAN

FOOD	AMOUNT (GRAMS)	CALCIUM (GRAMS)	PHOSPHORUS (GRAMS)	IRON MG.	IODINE MG.	VITAMINS					CALORIES
						A INTERNATIONAL UNITS	B_1	B_2	C INTERNATIONAL UNITS	D

Fats and sugar	as needed										

Undernutrition.—The fact that there are individuals in this country living on a restricted diet shows that even in a well-organized social system, undernourishment is present. In certain poorly organized systems, the majority of individuals are not only undernourished, but are continually threatened with famine. For example, a folk saying in Russia, "May God grant us an increase of our cattle and many child deaths," arises from the many famines that have occurred in that country. In recent years, Russia has had famines (in 1891, 1906, 1911, 1920-1922 and 1931-1932) in which millions have starved. Ireland, India, and China also have had many famines. In fact, man's history has been largely a struggle for food. In this respect historical accounts are often er-

roneous, for they seldom describe the amount of food available to the common man but merely relate the banquets of the nobles. Indeed, it has been stated that it was not until the end of the eighteenth century that man began to escape from the sole aim of obtaining sufficient food. Even now, man lives on a narrow margin. Four years of war and several revolutions in Germany produced the results shown in Table LXXXIX. Five years later matters were even worse. Obviously these conditions are of great physiological interest, and important information results from studies on large numbers of individuals suffering from starvation.

Starvation may be acute or chronic, and may be subdivided into several types. For example, one may speak of oxygen starvation or anoxia, fat starvation resulting from lack of fat in the diet, water starvation from lack of water, and vitamin starvation from vitamin deficiency. In fact, man can starve for lack of any of the essential food materials. However, the term generally implies *caloric starvation.*

Acute Caloric Starvation.—Man has gone for as long as fifty days without food. The most thorough study of the effect of acute starvation is that of Benedict.[490] A summary of his results is given in Table LXXXVIII. It may be seen from this table that with the decrease in weight, there is a decrease in total metabolism. The body conserves salts by decreasing the output of sodium and chloride. The subject was in ketosis, as may be seen from the output of β-hydroxybutyric acid. Hemoglobin concentration of the blood was maintained at a normal level. There was a slight fall in body temperature and pulse rate. These are the major effects of acute starvation.

TABLE LXXXVIII

THE PHYSIOLOGICAL AND BIOCHEMICAL CHANGES DURING FASTING (BENEDICT[490])

DAYS OF FASTING	1	11	21	31
Body weight, kg.	59.60	53.88	50.49	47.39
Rectal temp.	——	36.54	36.04	35.96

Cal. per sq. meter body surface per 24 hours	843.0	732.0	653.0	701.0

Chronic Caloric Starvation.—In Germany at the start of the war of 1914-1918, a committee determined that the population could exist without serious disturbances on the diet of 1,985 calories given in Table LXXXIX. For many reasons, however, the people never obtained this diet but were given one containing only 1,344 calories per day. Naturally, chronic starvation afflicted most of the population. The physiological changes are of interest (von Muller,[498] Lusk[495]). In the first place, there was marked loss of weight, and with this loss of weight there was a decrease in diseases associated either directly or indirectly

TABLE LXXXIX

DIET PER CAPITA PER DAY FOR WINTER OF 1916-1917 IN GERMANY (LUSK[495])

	AS PLANNED			AS PROVIDED		
	AMOUNT GRAMS	PROTEIN GRAMS	CALORIES	AMOUNT GRAMS	PROTEIN GRAMS	CALORIES
Bread	271.0	17.2	688	271.0	17.2	688

Sugar	32.0	—	125	26.0	—	104
Cereals	—	—	—	9.8	0.9	31
Totals	—	53.8	1,985	—	31.1	1,344

with overeating (gout, nephritis, and diabetes). There was also a lowering in basal metabolic rate. This shows an interesting adaptation on the part of the body, since the decrease was relatively greater than the loss of weight. In such cases, therefore, the body is compensating for the decreased intake by a decrease in output of energy. In cases of long continued starvation edema, gangrene around the mouth (noma), and osteomalacia developed. The edema may have been due to lack of blood proteins and the osteomalacia to lack of vitamins.

There were also marked psychological changes: depression and disinclination to work or play. In fact, every movement was reduced as far as possible to meet the reduction in caloric intake. Serious social changes, even cannibalism, have resulted from chronic starvation. Gantt[493] has described such a condition in Russia during a recent famine. It is little realized that our modern development rests on an adequate supply of food and that as soon as this becomes inadequate, man reverts to a lower form of society.

Obesity.—It is commonly recognized that there are two types of obese individuals: the overeating-underexercising type and the endocrine or constitutional type. The majority of cases of obesity are of the first type, as was demonstrated in Germany during the war of 1914-1918. For, as the report above shows, after several years of chronic starvation there were no obese individuals in that country. It is surprisingly easy to ingest more calories than needed. When one considers that a small piece of butter weighing 14 grams yields 100 calories and the maximal daily requirement is about 3,000 for moderate work, it is easy to understand how most individuals have a positive caloric balance and gain weight. Tables showing the normal weights for the various heights have been constructed, and the use of such tables gives an index of treatment. The standards used by the Army Air Corps are given in Table XC (Armstrong[489]).

The treatment of the most common type of obesity is obvious but difficult. Caloric intake should be reduced, and the amount of exercise increased. It has been calculated that, walking at the rate of five miles an hour, it would be necessary to cover a distance of 34.75 miles to rid the body of one pound of fat. The additional difficulty is that exercise increases appetite, which, if satisfied by extra food, soon counteracts the effect of exercise. The more rational treatment is a gradual reduction of food intake. A factor which must be considered in such reduction is the retention of water. Newburgh and Johnston[499] noted

TABLE XC

STANDARDS OF HEIGHT AND WEIGHT (ARMSTRONG[489])

HEIGHT	WEIGHT ACCORDING TO AGE PERIOD			
INCHES	20-25		26-30	
	STANDARD	MINIMUM	STANDARD	MINIMUM
64	128	115	131	116
66	136	121	139	124
68	144	129	147	132
70	152	137	155	140
72	160	145	164	149
74	168	153	174	159
76	176	161	184	169
78	184	169	194	179

that a patient weighing 231 pounds lost no weight for several days after being placed on a starvation diet. In fact, it was thirteen days before the actual weight reached the expected level. Water balance studies in this individual demonstrated that the difference was due to water retention during the early part of the starvation period. Therefore, loss of body fat may be masked by water retention.

Adiposity may be produced by abnormalities in the function of the thyroid, pituitary, and sex glands. This type of obesity may result secondarily from overeating. The primary change in the hormonal control may affect the individual so that the normal ratio between needs of the body and caloric intake may be disturbed, with the result that the patient overeats.

The Role of Inorganic Salts in Animal Nutrition

Inorganic salts are just as necessary as organic foodstuffs for the maintenance of life. The absence in the diet of those needed in the smallest traces is just as incompatible with life as is the absence of those that are required in abundance. In fact, certain of the elements ingested in the food material play such a prominent role in the regulation of metabolism that they may be looked upon as inorganic vitamins.

The inorganic salts may be divided into two groups. The first are those that are needed in relatively large quantities to supply the important ions of the body for the maintenance of normal osmotic pressure, to regulate the hydrogen ion concentration, or to provide structural materials. The second are those that are needed in small quantities and act as regulators of metabolism. The latter group, the inorganic vitamins, are called "trace" elements. In the first group are the chlorides, phosphates, and sulfates which form the anions of the body fluids, as well as sodium, potassium, calcium, and magnesium which form the positive ions or cations. Some of these elements, like calcium, are used for structural purposes. Iron and iodine must be included in this group, for they enter into the structure of hemins and thyroxin, respectively. In the second group are a large number of elements such as aluminum, bromine, cobalt, copper, iron, manganese, nickel, zinc. The functions of this class are not as well defined as those of the first group since their roles are revealed only by deficiencies or excesses of the elements in a diet. Many other elements have been shown to be present by spectroscopic analyses of ash from the animal body.

Whether these are essential in animal metabolism or merely contaminants from the utilization of vegetable food material is not known.

Inorganic Salt Content of Foods.—In the case of man, the inorganic salts, with the exception of sodium chloride, are contained usually in adequate quantities in the natural foodstuffs. However, animals fed and developed for the production of food may need the addition of minerals to their diets for successful nutrition. The quantity of inorganic salts obtained with natural foodstuffs varies tremendously. Some foods, such as white flour, sugar, and cornstarch, contain practically no mineral elements, while milk, green vegetables, and meat are rich in these materials. The inorganic salt content of some of the commoner foodstuffs is given in Table XCI. Recent dietetic surveys have

TABLE XCI

CONTENT PER 100 GM.* OF THE MORE IMPORTANT MINERALS OF CERTAIN FOODS IN THE FRESH STATE

(Compiled from Sherman's tables.)

FOOD	CALCIUM MG.	PHOSPHORUS MG.	IRON MG.	SODIUM MG.	POTASSIUM MG.
Beef (lean)	0.007	0.218	3.0	0.084	0.338
Eggs	0.067	0.180	3.0	0.143	0.140

Cabbage	0.045	–	1.1	0.027	0.247
Carrots	0.056	0.046	0.6	0.101	0.287
Potatoes	0.014	0.055	1.3	0.021	0.429
Apples	0.007	0.012	0.3	0.011	0.127
Oranges	0.045	0.021	0.2	0.012	0.177
Prunes (dried)	0.054	0.105	3.0	0.069	1.030
Watercress	0.187 (?)	0.005	1.9	0.099	0.287

*It is obvious that these values will vary considerably for most of the foods. For instance, in the meats they will depend on the amount of fat (which is nearly salt-free), and in vegetables with the mineral content of the soil upon which they are grown. When any degree of exactitude is required, as in making surveys of the mineral content of dietaries in a community, it is necessary that several of the available foodstuffs be subjected to special analysis.

shown that the danger of an adequacy in inorganic salt consumption is not frequently incurred, especially among the members of the poorer classes living in large cities, who consume large quantities of bread but inadequate amounts of milk, eggs, green vegetables, and meats. The function of some of the more important inorganic elements will now be separately considered.

Sodium and Potassium.—Both of these elements occur as chlorides, phosphates, and carbonates and in combination with simple organic acids, such as hydroxybutyric or lactic, and with the carboxyl group in large molecules of proteins and other complex compounds. Sodium is the chief cation of the body fluids, while potassium is found chiefly in the cells (see Chapter LXXVIII). Sodium chloride is responsible for maintaining the correct osmotic pressure of the body fluids, although other soluble constituents aid in its regulation. It is excreted constantly, chiefly in the urine. In order to maintain its store in the organism, fresh supplies, amounting to nearly two grams a day, must be taken with the food. During prolonged fasting, the excretion may become very low; for example, it fell to 0.13 grams per day in the fasting man studied by Bene-

diet (page 834). St. John[527] found that amounts of sodium below 0.3 per cent of the total food intake were inadequate for growth in rats. The ordinary intake of plant and animal tissues contains an abundant supply of potassium. Experimentally, Miller[522] has shown that rats fail to grow and eventually die when the daily intake of potassium is 1.0 mg. or less. For normal growth, male rats require as much as 15 mg. per day, while females require only 8 mg.

Calcium.—In the blood of adult human beings, the calcium concentration is maintained at 10 mg. per 100 ml. of blood. This calcium level represents a balance between absorption from the intestine, excretion in the feces and urine, and deposition in the bones and teeth. The parathyroid glands control calcium metabolism; removal of these glands causes the blood calcium to fall and, if extracts of the parathyroid glands are injected, the calcium content rises. According to Peters and Van Slyke,[506] the normal serum calcium may be considered to be made up of: a small portion held in solution by forces which govern solubility in salt solutions; a portion held in solution by serum proteins; and a portion which remains in solution either by virtue of the retarded precipitation that is characteristic of supersaturated solutions of calcium carbonate and phosphate or by the formation of complexes.

A decrease in calcium ions or an increase in potassium ion causes an augmentation of irritability not only in the heart muscles but also in skeletal muscle. In fact, if these changes are pronounced, tetany develops. Shohl[509] has classified the types of tetany in the manner shown in Table XCII.

TABLE XCII

TYPES OF TETANY (SHOHL[509])

	Ca	Ca^{++}	PO_4	CO_2	pH
1. Low calcium					
Rachitic	low	low	high	normal	normal
Low calcium intake	low	low	high	normal	normal
Parathyroid	low	low	high	normal	normal
2. High phosphate	low	low	high	normal	normal or elevated
3. High bicarbonate	normal	?	?	high	elevated
4. Hyperventilation	normal	?	normal	normal	elevated
5. Citrate	high	low	normal (?)	normal	normal
6. Low magnesium	normal	normal	normal	normal	normal

An interesting biological approach to this problem was made by McLean and Hastings[520, 521] who used the amplitude of heat of the frog's heart to determine the concentration of calcium. From this work it became clear that the protein of the serum is the main factor in the ionization of calcium. The dissociation constant may be determined by

$$\frac{[Ca^{++}] \times [protein^{--}]}{[Calcium\ proteinate]} = K$$

or conversely $[Ca^{++}]$ may be calculated from the combination of total calcium and protein. The value of K is given as $10^{-2.22}$. In addition to these physiological functions, calcium is preeminently the skeletal element of the body and plays a role in the clotting process. The calcium requirement for man averages about 0.45 gram per day (Sherman[500]).

Phosphorus.—The physiological importance of this substance in the animal is indicated by its widespread presence in many parts of the organism and in its many physiological uses. It is present in large amounts in the bones and forms, in the blood, monobasic and dibasic salts which are of importance as buffer substances. Compounds of phosphoric acid with organic radicals are very common, for example, the phospholipids which are present in nearly all tissues. United with purine bases, phosphoric acid enters into the structure of nucleic acids and, in muscle, unites with creatine to form phosphocreatine. The combination of phosphoric acid with hexoses is a very important intermediate compound in carbohydrate metabolism. Deficiency of phosphorus in a young animal produces rickets. The deposition of calcium and phosphorus in the bones appears to depend not so much on the absolute concentration of either in the blood as on the proportion between the two. Therefore, any change in the amount of phosphorus in the blood must be correlated with the concentration of calcium.

Recent interest in phosphorus metabolism has resulted from the introduction of radioactive phosphorus. This isotope (see page 723) which has a half life of 14.8 days, is easily prepared and detected. Cohn and Greenberg[511] studied the rate at which different organs absorb phosphorus. They found that heart, kidney, and liver absorb phosphorus very quickly. Hahn, Hevesy and Lundsgaard[513] have found that radioactive phosphorus remains in the body about thirty days.

Phosphorus is an essential in the diet. Osborne and Mendel[525] have demonstrated that rats do not grow on a phosphorus-deficient diet. Sherman[500] states that 0.88 gram of phosphorus per day is the minimal amount for a positive balance in a man of average weight.

Iron.—Iron enters into the formation of hemoglobin and of certain tissue pigments. An adult man requires in his food about 15 mg. of iron per day. Iron is absorbed through the duodenum in the ferrous form and is excreted by the large intestine and cecum. It is stored in the liver. The study of the metabolism of iron has been aided by the use of a radioactive isotope of this substance. Whipple and his associates[514] have demonstrated that the amount of radioactive iron that is absorbed depends on the need of the body for iron. Radioactive iron was found inside the red blood cells three hours after ingestion. Small amounts were also detected in the liver and bone marrow.

Sherman[500] states that 15 mg. a day may be considered the standard allowance. It is very difficult, however, to make exact balance studies with iron salts, because iron is held in storage in the body for a long time after ingestion.

A very interesting synergism between iron and copper is brought out in the cure of the anemia which results from a diet deficient in these elements. Hart and his associates[517] have shown that purified iron salts fed to rats on a milk diet are ineffective in stopping the progressive anemia. If the iron is fed as an ash of lettuce, yellow corn, or beef liver, the hemoglobin level is restored to its normal value. It was found that this restoration depends on the presence of a trace of copper. The exact role played by copper in the formation of hemoglobin is not known. It does not enter into the molecule but may act as a catalyzer of some of the intermediate reactions in hemoglobin formation. The common natural sources for iron are liver, kidney, eggs, fish, oysters, spinach, and oatmeal.

Iodine.—Iodine is present in minute traces in all of the tissues. It is present, however, in large amounts only in the thyroid gland where it becomes an

integral part of thyroxin. Goiter develops in individuals receiving insufficient amounts of iodine. Sea foods are rich in iodine; oysters especially contain a large amount of this substance.

Radioactive iodine has recently been used in metabolism studies. Hamilton[515] has found that this substance is absorbed very quickly. It may be detected in the body within three to six minutes after ingestion, and absorption is complete in three hours. In a later study, Hamilton and Soley[516] demonstrated that the thyroid gland in patients suffering from goiter takes up radioactive iodine.

Magnesium.—In the plant world, magnesium occupies the important place which iron holds in the animal kingdom, for magnesium is as essential an inorganic element in the chlorophyll molecule as iron is in the hemoglobin molecule. Its exact function in the animal body is not completely understood. It does enter into the composition of bone and may replace calcium in that structure. It is present in blood. Magnesium also plays a role as a coenzyme in glycolytic systems (Chapter XLVIII).

Magnesium is essential to the life of an animal. McCollum and his associates[519] have shown that electrical stimulation of rats on low magnesium diets resulted in spontaneous convulsions and tetany. Sherman[500] states that the average American diet contains about 0.27 gram a day. This is sufficient for a positive balance since it has been demonstrated by Tibbets and Aub[526] that 0.22 gram was adequate.

Borsook and his associates[519] have studied the metabolism of sulfur with a radioactive isotope. Following the feeding of 202 mg. of this form, 15 per cent appeared in the urine in the first nine-hour period after ingestion, and 32 per cent in the period from nine to twenty-four hours after ingestion. Therefore, only 47 per cent of the radioactive sulfur was excreted. These authors conclude that there is continuous exchange of sulfur in the tissues.

Other Inorganic Elements.—In this group are manganese, fluorine, copper, bromine, nickel, and zinc. Orent and McCollum[523] have shown that manganese is essential to the rat. On a manganese-free diet, the males underwent testicular degeneration, and the females lost interest in their young and did not give them an opportunity to suckle. The chief sources of manganese are milk, bran, and nuts. Everson and Daniels[512] state that children should have from 0.2 to 0.3 mg. per kilogram of body weight per day.

The quantity of fluorine ingested is of importance, because overdoses produce chronic poisoning. In rats, the symptoms of this condition are brittle and opaque teeth, and, in human subjects, a mottling of the enamel. This condition appears in regions in which there is more than 2.5 mg. of fluorine per liter of drinking water.

Cobalt, copper, and zinc are also essential. The important role of copper in the formation of hemoglobin is discussed in the section on iron. An excess of cobalt, fed in combination with copper, produces polycythemia in rats (Orten et al.[524]). Zinc is also essential for life (Howe et al.[578]). This element is found in large concentrations in the pancreas and it aids in the *in vitro* crystallization of insulin.

CHAPTER LVIII

THE PHYSIOLOGY OF MUSCULAR EXERCISE

During muscular exercise, the increased demand for oxygen by the active muscles and the need for carrying away the waste products of metabolism from the muscles bring into action many of the systems of the body. Therefore, the physiology of muscular exercise illustrates the correlation of the functions of the respiratory, nervous, muscular, and other systems and demonstrates how the various organs adapt themselves to the tremendous demands placed on them during muscular work. These adaptations are important not only as a physiological study but also as a practical basis for the measurement of man's ability to produce useful work. A thorough knowledge of this subject enables a physician to evaluate the ability of a patient to work. This is important to a doctor, as the first question asked him by a recovering patient is usually, "When may I get up and go back to work?"

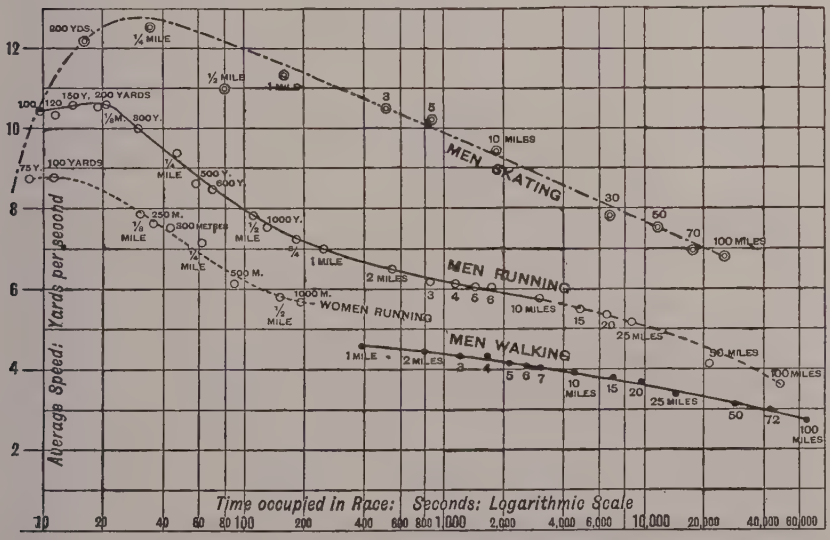

Fig. 303.—Relationship between speed and total time occupied in race. (From A. V. Hill: Living Machinery, New York, 1927, Harcourt Brace and Company.)

Man and animals have developed adaptations for exertion to a remarkable degree. Athletes have been able to propel themselves 100 yards in less than ten seconds and have been able to walk 100 miles in twenty-one hours and thirty-six minutes. These records are remarkable demonstrations of speed and endurance. The times for running various distances by man are given in Fig. 303. These curves illustrate that there is a definite relationship between speed and duration of endeavor. It is the purpose of this chapter to discuss

the adaptations of man to exercise and to define the limiting factors governing the ability of man to carry out muscular endeavor. Not all of this information covering the interactions of the various systems has been obtained under conditions of muscular exercise in man. Many types of animal experimentation have contributed to this knowledge. It is reasonable to suppose that certain mechanisms, such as the Bainbridge reflex (see page 469), which has been shown to go into action in the resting anesthetized animal, will also operate in the intact working animal. Therefore, results from such experiments may be applied to man. The final decision, however, must await results obtained in experiments made on the exercising animal or on man.

RESPIRATORY METABOLISM

The fundamental change during muscular exercise is the increased metabolism of the skeletal muscles. This involves a greatly augmented consumption of oxygen, the quantity used depending on the amount of work (Fig. 304).

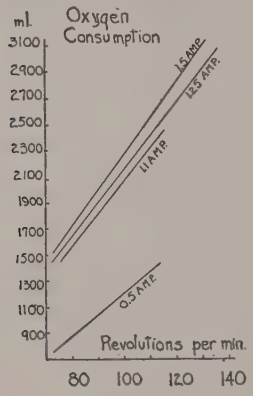

Fig. 304.

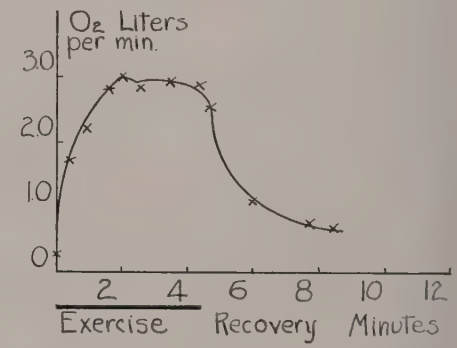

Fig. 305.

Fig. 304.—Relationship between the oxygen consumption and the amount of work done (revolutions of bicycle wheel per minute with subject pedalling with different loads). (From Benedict and Cathcart: Carnegie Inst. of Washington, Publ. No. 187, 1913.)

Fig. 305.—Oxygen consumption during and after exercise. (Redrawn from Furusawa: Proc. Roy. Soc. B. 99: 148, 1926.)

In the chapter on The Chemistry of Muscular Contraction (Chapter LII) a description was given of the utilization of oxygen by isolated muscle during and following stimulation. In these preparations it was found that there are two phases of the augmented oxygen consumption; the one occurs during the muscular contraction and the other after the contraction. Similar results are obtained when the oxygen consumption is measured in man during and after muscular exertion (Fig. 305). The phase occurring during muscular exertion may be subdivided into two parts, the initial rise and the "steady state." The fact that the metabolism does not rise immediately to the final plateau indicates that there is a slight lag in the circulatory and respiratory adjustments at the beginning of exercise. The plateau is soon reached, and this part of the curve is called the "steady state." It may be defined as the condition in which the intake of oxygen meets the metabolic needs of the muscle. On this

plateau, the respiratory and circulatory adjustments are sufficient to meet the need. Under the condition of light muscular exercise, the recovery period is of short duration and of such magnitude as to compensate for the lag in oxygen intake at the start of the experiment.

These facts apply only to moderate muscular exercise, because, if the severity of the exercise is increased, a point is reached where the intake of oxygen no longer keeps pace with the metabolic needs. At this point, the relationship between the oxygen requirement for work and the intake of oxygen changes (Fig. 306). Therefore, the first limiting factor is the maximal amount of oxygen that an individual may take in per minute. This is conditioned by the efficiency of the respiratory and circulatory systems. Generally it is about 4.0 liters per minute but values as high as 5.1 have been recorded (Robinson, Edwards and Dill[601]).

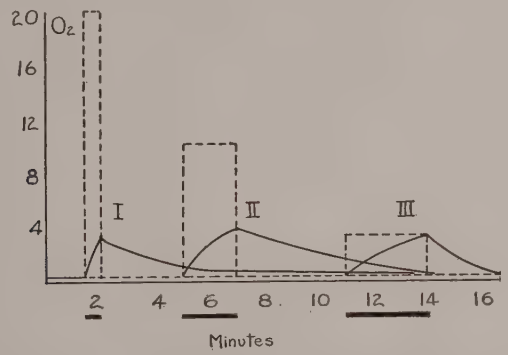

Fig. 306.—Diagram illustrating the difference between the oxygen requirement and the oxygen intake. Areas under broken lines: oxygen requirement in liters. Areas under solid lines: oxygen intake in liters. I, severe exercise; II, moderate exercise; III, light exercise. Duration of work given by heavy black lines. (From Furusawa, Hill, Long and Lupton: Proc. Roy. Soc. B. 97: 167, 1925.)

Man can continue to increase the intensity of work which demands more energy than can be supplied by his maximal oxygen intake during the work. This is done by increasing the recovery period. This phase of oxygen utilization becomes greater as the intensity of effort is increased. Hill has termed the amount of oxygen used during the recovery period the *oxygen debt,* for it indicates to what degree the body has gone into debt during the exercise,

TABLE XCIII

OXYGEN REQUIREMENTS FOR RUNNING 120 YARDS AT DIFFERENT SPEEDS (SARGENT[605])

SPEED (YARDS PER SECOND)	OXYGEN REQUIREMENT	
	LITERS PER 120 YARDS	LITERS PER MINUTE
5.56	1.83	5.08
6.45	2.71	8.75
7.15	2.94	10.50
7.24	3.08	11.13
7.70	3.85	14.81
8.40	4.33	18.17
9.10	6.27	28.46
9.23	7.36	33.96

a deficiency which must be made up after the exercise is over. Sargent[605] has shown experimentally that the oxygen debt may be as high as 16.3 liters. Values for the oxygen requirements for running at various speeds are given in Table XCIII.

Lactate Production.—The ability of man to go into oxygen debt is dependent, in part, on lactate production. Large amounts of lactate are found in the blood and urine of man immediately after strenuous muscular exercise. Hill and his associates[576] have recorded amounts as high as 204 mg. per cent (normal, 10 mg. per cent) and Liljestrand and Wilson[589] have found 1,370 mg. in the urine after exercise. Hill considered that the extra oxygen taken in during the recovery period was used only for oxidation of lactate produced during the exercise. However, this question has been reinvestigated by

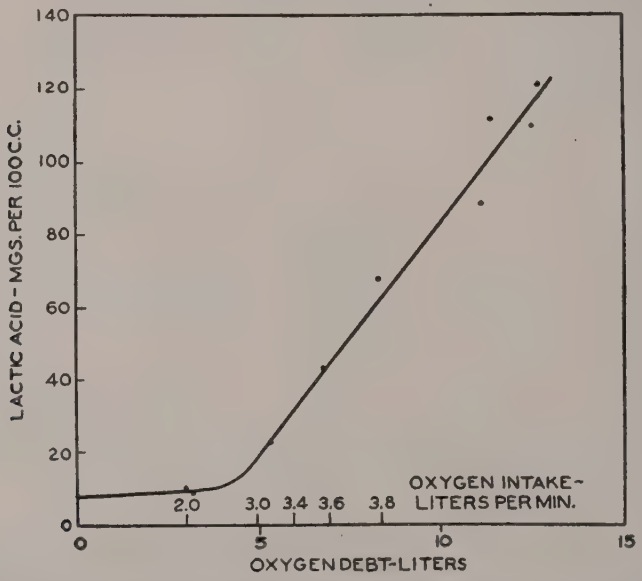

Fig. 307.—Relationship between lactic acid concentration in the blood and oxygen debt. Duration of exercise was ten minutes in each case. (From Margaria, Edwards and Dill: Am. J. Physiol. **106**: 689, 1933.)

Margaria, Edwards and Dill.[592] They found that a certain amount of oxygen debt may be increased without the appearance of lactate in the blood. When the oxygen debt reaches three or more liters, however, there is a direct relationship between the amount of lactate in the blood and the magnitude of the oxygen debt (Fig. 307). Therefore, the recovery period is made up of two phases, an alactacid debt which may be related to the oxidation of the usual food materials metabolized for the production of energy, and the lactacid debt which may be correlated directly with the oxidation of lactate.

Any experiments, however, of this nature in which blood concentrations are related to total energy exchange involve the assumption that there is an equal distribution of the material under study between tissues and blood. Sacks and Sacks[603] have stated that such conditions do not exist in cat's muscle, because the muscle lactate may be as high as 324

mg. per cent when the venous blood lactate is only 59 mg. per cent. These experiments indicate that measurement of blood lactate would not give any idea of the total amount of lactate in the body and any correlation between blood concentrations and oxygen consumption would be devoid of meaning. Newman,[596] however, has shown that in the rat there is a strict relationship between blood and tissue lactate concentrations.

These divergent results suggest that there may be a species difference. Therefore, the exact interpretation of the relationship of lactate concentrations in the blood and oxygen utilization by man during the recovery period must await a more complete analysis.

Sacks, Sacks and Shaw[602] have shown that for moderate degrees of muscular contraction there is always some lactate formed at the beginning of the period of contraction, but that this value soon falls off if the speed of contraction is not too great. This can only mean that the first phase of muscular contraction is anaerobic, since the respiratory and circulatory adjustments do not meet the need for several seconds after exercise has started. The work of Millikan[595] also illustrates this point. The muscle hemoglobin becomes reduced even when the blood supply is intact, thus proving that the demand for oxygen is greater than the supply.

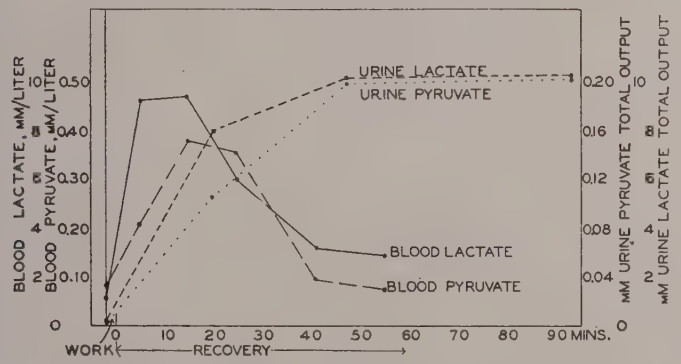

Fig. 308.—Relationship between lactate and pyruvate in blood and urine after hard running. (From Johnson and Edwards: J. Biol. Chem. 118: 427, 1937.)

The ability of the body to withstand the production of lactate is another limiting factor in muscular exercise. Recovery periods of 15 liters of oxygen have been reported. This indicates that a man can exercise to the degree at which he needs 20 liters per minute, five liters being taken in during the exercise and 15 liters afterwards. If he exercises for ten minutes, he must reduce the severity of the exercise, for he would have available only 6.5 liters per minute for his work: $\frac{10}{(5 \times 10 + 15)} = 6.5$. The relationship between the duration and velocity of work can be explained on this basis. For short distances, the runner may depend mainly on his recovery period; for long distances, he must run in a steady state and the metabolic cycles must be completed during the exercise. For moderate distances, the runner may depend on both factors. These facts are illustrated in Fig. 303. In this diagram the curve relating speed and duration is horizontal for short runs, falls off for moderate distances and again flattens out for long distances.

Pyruvate.—Pyruvate also appears in the blood and urine. The concentrations of pyruvate are very small in relation to the amounts of lactate. Johnson and Edwards[580] found that the ratio of lactate to pyruvate was thirty-seven five minutes after a strenuous run. Their results are given in Fig. 308.

EFFICIENCY OF MUSCULAR WORK

One of the important relationships obtained by the study of the total metabolism during and after work is the "efficiency" of man. This factor may be determined by relating the total energy to the output of mechanical energy. In this relationship the base line used is zero. Other base lines have been prepared: the basal metabolism, the metabolism of the subject sitting on the bicycle ergometer, and the metabolism of the subject pedalling without any resistance in the brake system. These values are subtracted from the total

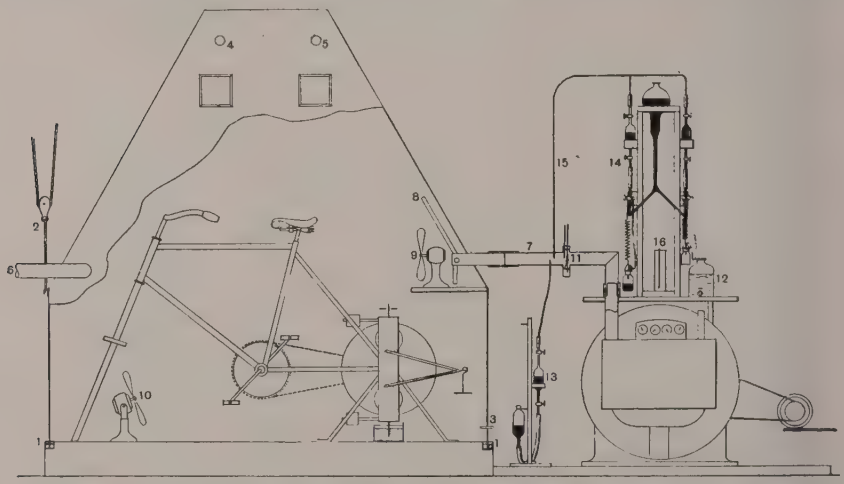

Fig. 309.—Bicycle ergometer, meter, and gas sampler. (From Krogh and Lindhard: Biochem. J. 14: 290, 1920.)

energy and are used in the calculation of a "net efficiency." Such a calculation indicates that the metabolism of work is an increment over a constant basal level. It is doubtful whether such a base line would remain constant during exercise. For example, some of the metabolic activity during rest is used to maintain body temperature. During work, there is a great excess of heat produced and it is dubious whether the body would continue to produce the basal amount of heat under such circumstances. Therefore, the best factor to use is the total output of energy in which the base line used is zero. However, if any other base line is used, the efficiency must be qualified by indicating what base line is involved in the calculations. Of numerous methods of measuring the mechanical energy developed by man during exercise, the most common is the bicycle ergograph (Fig. 309). The efficiencies of horses, men, and motors are given in Table XCIV. It is clear that another limiting factor in

the ability of man to carry out work is his power of converting only about 25 per cent of his total energy intake into useful external work.

TABLE XCIV

MAXIMAL EFFICIENCY OF HORSES, MEN AND MOTORS (BRODY AND TROWBRIDGE[544])

MOTIVE POWER	EFFICIENCY PER CENT
Steam Engines	15
Gasoline Engines	18
Horse	24
Man (stair climbing)	25
Diesel Engine	35

The maximal efficiency obtained in any process depends on the speed at which this process is carried out. This relationship has been determined for numerous types of work. The results of one such set of experiments are given in Table XCV in which the efficiency of man while pedalling a bicycle was determined. This relationship between speed of muscular movement and efficiency has important industrial application, since the highest efficiency of man may be obtained only over a very narrow range of speed of working. Not only does the speed of working affect the efficiency, but also the amount of work. Garry and Wishart[561] found that, with a light load on the bicycle, the efficiency was 13.9 per cent at 45 revolutions per minute. Increasing the load but keeping the speed constant, raised the efficiency to 16.0 per cent.

TABLE XCV

GROSS EFFICIENCIES OF MAN PEDALLING A BICYCLE AT VARIOUS SPEEDS WITH THE SAME LOAD (BENEDICT AND CATHCART[542])

REVOLUTIONS PER MINUTE	GROSS EFFICIENCIES (IN PER CENT)
70	20.6
80	20.0
90	19.2
100	18.4
110	17.6
120	16.9
130	16.1

The Respiratory Quotient During Work.—With the rise in oxygen consumption there is a corresponding increase in the carbon dioxide output. The change in the relation between these two variables, the respiratory quotient, has been studied extensively during muscular work. At the present time it is thought that moderate exercise does not change this quotient from the basal level. In the case of strenuous exercise, however, there is considerable disagreement among the investigators of this subject. The difficulty of obtaining an exact measurement of the respiratory quotient during severe exercise is due to the changes in the lactate content of the blood. Since this is a fixed acid its production results in the expulsion of carbon dioxide from the blood. Later, when the lactate is oxidized, there is a retention of carbon dioxide. Therefore, to determine the metabolic respiratory quotient, it is necessary to make collections of expired air *throughout the complete recovery period.* Hill and his associates (see Furusawa[560]) used the "excess respiratory quotient" as a measure of the metabolism during work. The quotient was obtained by subtracting from the total oxygen inspired and

total carbon dioxide expired during and after exercise the oxygen and carbon dioxide that the subject would have used and expired had he remained at rest during the same period of time. This calculation implies that the ratio of the carbon dioxide production and the oxygen consumption over and above the basal level will give a true combustion quotient for the period of work. The values obtained for this excess quotient averaged 1.01, and indicated to these authors that carbohydrate is the source of energy for muscular exercise in man. The difficulty in accepting the "excess respiratory quotient" as a basis for calculation lies in the fact that there is no evidence that the energy exchange of the "basal" metabolism remains the same in work or that the excess metabolism of work is exactly related to the increment over the basal level. Therefore the total respiratory quotient of exercise seems a better criterion of metabolism than the "excess quotient." Gemmill[563] determined the total respiratory quotients of men after they had run seventy yards in ten seconds on a treadmill. In these subjects the respiratory quotient including that of a complete recovery period was practically the same as the basal values. Dill and his associates[555] found that after severe muscular work the arterial carbon dioxide content did not return to the normal level during a two-hour recovery period. When the respiratory quotients were corrected for this shift in carbon dioxide tension, the "excess quotients" for the entire period of work and recovery were between 0.9 and 1.0. Christensen and Hansen[550] have found quotients of 0.95 with their subjects working at such a rate that 4.15 liters of oxygen were used per minute. These experiments show that some men working under very strenuous conditions have respiratory quotients less than unity for the metabolism during and after work.

THE FUEL OF MUSCULAR EXERCISE

Discussion of the respiratory quotient raises the question of the type of material oxidized by man in order to provide the energy for the muscular exertion. Liebig[587] observed a small increase in nitrogen in the urine after muscular work and from this observation concluded that protein catabolism supplies the energy for muscular contraction. Fick and Wislicenus,[559] however, calculated that the total amount of energy liberated during work is much more than that coming from the oxidation of protein. This conclusion has been confirmed by Cathcart[547] (Table XCVI). Although the metabolism of protein may be

Table XCVI

Effect of Muscular Work on Protein Metabolism (Cathcart[547])

	TOTAL NITROGEN OUTPUT IN GRAMS			
	EXPERIMENTS			
	I	II	III	IV
Pre-work (average, 4 days)	8.78	17.31	17.40	14.30
Work (average, 6 days)	10.01	19.96	18.23	15.44
Post-work (average 4 days)	9.05	17.76	17.34	16.34

responsible for a very small portion of the total metabolic change during exercise, other nitrogenous compounds, such as phosphocreatine and adenylpyrophosphate, have been shown to be of importance in muscular contraction. The

relationship of these substances to muscular work in the isolated muscle has been described in the chapter on the chemistry of muscular contraction (Chapter LII).

The question now arises as to the relative importance of the metabolism of fat and carbohydrate in supplying the energy. Benedict and Cathcart,[542] on the basis of their extensive study of the metabolism during muscular work, concluded that the more severe the muscular effort the more carbohydrate is oxidized but that exercise is not carried out exclusively at the expense of carbohydrate combustion. Krogh and Lindhard[584] also suggested that the energy for muscular work is obtained from the oxidation of both fat and carbohydrate. Recent work has substantiated the views of these observers. For example, Edwards, Margaria and Dill[557] observed that the respiratory quotient decreases with successive periods of work. From this observation they concluded that more fat is needed when the carbohydrate supply is diminished and that carbohydrate is no more essential for the metabolism of work than it is for energy exchange under basal conditions. Whether the fat must be transformed to carbohydrate before it is oxidized and whether fat may be utilized directly for muscular work are important questions that have not been satisfactorily answered at the present time.

TEMPERATURE REGULATION IN EXERCISE

Since only about 20 per cent of the energy expended during muscular exercise is converted into kinetic energy, the rest, about 80 per cent, is liberated in the form of heat. In order to lose this excess heat and to prevent an injurious rise in body temperature, various thermoregulatory mechanisms must go into action (see Chapter LIX). There is greater loss of heat through the respiratory tract associated with the increased ventilation of the lungs. Peripheral dilatation of skin vessels aids in loss by convection and radiation. The perspiration increases, allowing more water to be evaporated from the surface of the skin. Christensen, Krogh, and Lindhard[548] have drawn up a balance sheet for heat production and heat losses during exercise (Table XCVII).

Table XCVII

Balance of Heat Losses During Exercise (Christensen, Krogh, and Lindhard[548])
Work on ergometer for 180 min. at the rate of 1,080 kg. meters per min.

CALORIES PRODUCED		CALORIES EXPENDED	
Calculated from O_2 consumption	2,465	Mechanical work	472
		Rise in body tem.	107
		Lost by evaporation of water:	
		(a) through skin	956
		(b) through air passages	133
		Convection, radiation, and heating of inspired air	797
Total	2,465	Total	2,465

However, the thermoregulatory mechanisms cannot keep pace with the increased metabolic rate, for the body temperature rises somewhat during exer-

cise. Benedict and Cathcart[542] studied this rise during bicycle pedalling and obtained the results given in Fig. 310. It may be that the rise in temperature is an advantage to the body, as the velocity of metabolic processes would be increased and circulatory and respiration activity would be aided by this moderate change.

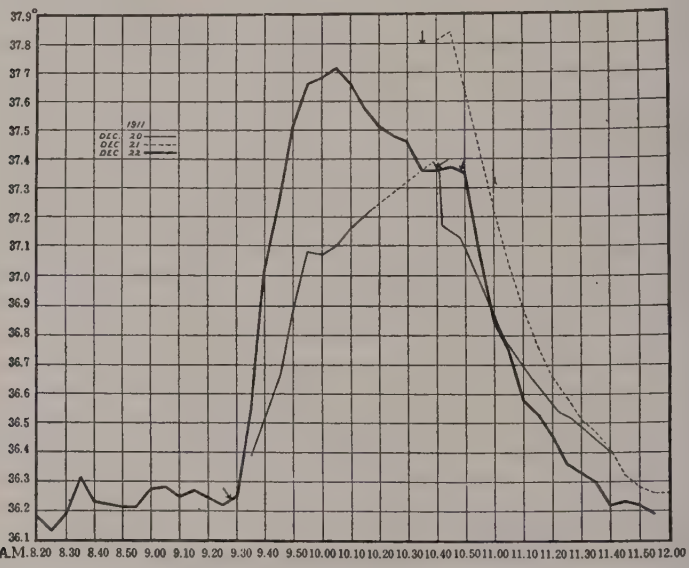

Fig. 310.—Continuous records of rectal temperature in a human subject during severe muscular work. (From Benedict and Cathcart: Carnegie Inst. of Washington, Publ. No. 187, 1913.)

BLOOD CHANGES

It is difficult in man to make direct analyses of the chemical changes in the muscles during exercise. Therefore, chemical studies must be confined to the blood and urine with the hope that the findings reflect the actual changes in the muscle. The difficulty of interpreting the results of blood analyses is that they represent only the transport of material to and from the active muscles. Nevertheless, some information concerning metabolic changes has been gained from these studies.

Numerous experiments have been made on the blood sugar content during exercise. Moderate work does not change the level of blood sugar, but if exhaustive work is carried out, the blood sugar may increase 10 to 66 per cent (Dill, Edwards and Mead[554]). If the exercise is continued for a long time, as in running a marathon race, the blood sugar may fall to very low levels (Levine, Gordon and Derick[586]). Numerous speculations have been offered to explain these results. It may be that during moderate work increased glycogenolysis in the liver keeps pace with the utilization of glycogen in the muscles and thus the glucose content of the blood remains constant. During more severe work

secretion of adrenalin may cause a more rapid liberation of glucose by the liver than is required by the muscles and, therefore, the blood sugar rises. However, if the exercise is extended over a long period of time, the supply of carbohydrate in the liver is exhausted and the blood sugar falls.

The lactate changes in the blood were discussed in connection with the oxygen debt. Laug[585] has correlated the changes in lactate, pH and the total CO_2 in venous blood during recovery from running 440 yards. Table XCVIII gives the results of a typical experiment.

TABLE XCVIII

CHANGES IN VENOUS BLOOD AFTER SEVERE EXERCISE (LAUG[585])

	PH	LACTATE (MG. PER CENT)	TOTAL CO_2 (VOL. PER CENT)
Resting	7.35	5.6	61.1
4'24" after running 440 yards	6.95	163.5	33.9
10'45" in 67.5 sec.	7.04	150.4	27.3

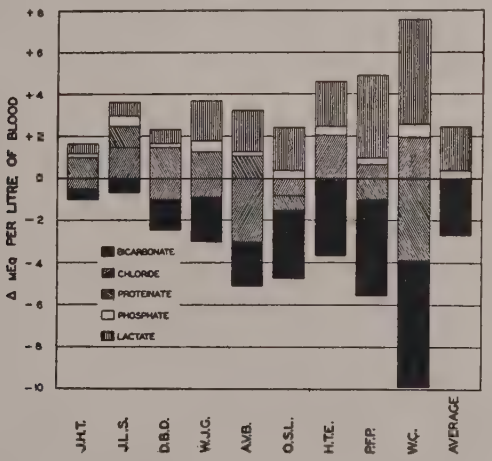

Fig. 311.—Changes in the principal anions of the blood serum during muscular work. (From Dill, Talbott and Edwards: J. Physfol. 69: 267, 1930.)

Gemmill[564] studied the changes in the acetone bodies after bicycle pedalling. No marked changes in these substances were found with the subjects on normal diets. However, on high fat diets there was a slight increase in these constituents following work. Changes in other blood constituents are summarized in Fig. 311. It is interesting to note that the concentration of the plasma proteins increases during exercise. These results may be accounted for by assuming a transfer of fluid from the blood to the tissues. However, the changes must be interpreted in the light of the severity of the exercise. There can be no doubt that in very severe exercise, with production of lactate in the muscles, there is a change in the water balance between blood plasma and tissues. During moderate work, in which lactate is not produced, there would not be the

necessity for this shift. Therefore, changes which are found during severe exercise cannot be transferred to all types of exercise.

There is an increase in the concentration of the red blood cells during work; the extent of the rise depends on the severity of the exercise (Table XCIX).

TABLE XCIX

THE EFFECT OF EXERCISE FOR FIVE MINUTES ON THE RED BLOOD CELL CONCENTRATION AND THE HEMOGLOBIN PERCENTAGE (SCHNEIDER AND CRAMPTON[606])

LOAD (FOOT POUNDS)	RED BLOOD CELLS (MILLIONS PER C.MM.)		HEMOGLOBIN (PER CENT)	
	REST	EXERCISE	REST	EXERCISE
4000	5.17	5.15	116	117
6000	5.16	5.43	115	120
8000	4.98	5.50	113	124
10000	5.16	5.80	114	127

Two theories have been proposed to account for these changes: (1) the red blood cells are forced into the circulation from reservoirs and (2) there is a change in concentration of the blood due to sweating, or passage of fluid from the blood into the tissues. Probably both factors, especially the latter, play a role in producing this change.

URINARY CHANGES

Wilson, Long, Thompson and Thurlow,[608] in a thorough study of the urinary changes following exercise, found that there is a decrease in urine volume and chloride concentration and an increase in hydrogen ions, total acid, ammonia and phosphate (Fig. 312). The drop in urine volume is due to a suspension of activity by the kidneys during exercise. It has been generally thought that this is due to a constriction of the renal vessels produced by the vasoconstrictor control. However, Verney and his associates[579] have obtained the same effect with the kidneys denervated. They postulate that the change in urine flow is due to the liberation of a hormone from the posterior pituitary during exercise. Further experimental work is needed before the exact mechanism of the decrease in urine formation can be explained. Factors which may operate are the change of water concentration in the blood and the increased loss of water through the skin and lungs.

The rise in acidity of the urine is explained by the increased acid excretion. Liljestrand and Wilson[589] have shown that as much as 1,370 mg. of lactate may be found in the urine after short periods of severe exercise. With this excretion of acid there is an increase in the ammonia output in an effort to save base. The mechanisms in the kidney for the production of ammonia cannot protect the body completely from the loss of base and some of these ions are lost. There is a slight increase in the phosphate excretion and the ratio of the disodium to the monosodium phosphate varies with the change in hydrogen ion concentration of the urine. Since this change is in favor of the monosodium phosphate, it also saves base. The small rise in phosphate excretion is probably a reflection of the changes in blood phosphate (Havard and Reay[571]). Since the mechanisms involving phosphate have been shown to be reversible in the isolated muscle, it is not surprising that the phosphate content of the

blood and urine does not change very much during and following exercise. In fact, Gemmill and Riberio[565] were unable to find that any change occurs in the blood phosphate of men as a result of running at maximum speed for ten seconds. The fall in chloride concentration may be due to the loss of chloride in the sweat and the shift of chloride with water from the blood into the active muscles. As in the case of blood changes, these urine changes found after severe exercise of short duration may not occur when man is exercising at a moderate rate of speed. They do illustrate, however, how the body is able to adjust itself to strenuous exercise. Moderate exercise may not call forth all these readjustments.

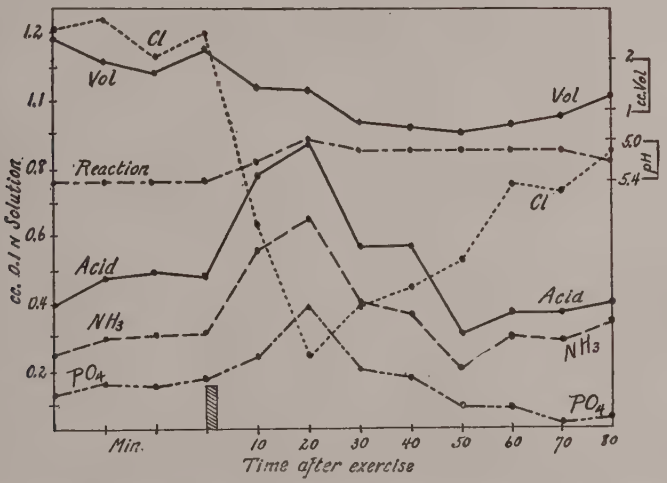

Fig. 312.—Chemical changes in the urine during and following severe exercise. (From Wilson, Long, Thompson and Thurlow: J. Biol. Chem. 65: 755, 1925.)

RESPIRATORY CHANGES

The total ventilation of the lungs increases with the demand for oxygen. The regulation is so exact that the value for the total ventilation is directly proportional to the utilization of oxygen (Fig. 313). For a given amount of work, there are two phases of the respiratory changes, a rapid initial increase followed by a slow rise to the final value which is maintained throughout the exercise. Since the onset of the initial phase is very rapid, occurring before any metabolites could affect the respiratory center, Krogh and Lindhard[583] have claimed that it is dependent on the higher centers sending impulses to the respiratory center at the same time that motor impulses are sent to the muscles. The final value reached depends on the severity of the exercise. The usual explanation of the change in ventilation during exercise is that the increased production of carbon dioxide raises the carbon dioxide tension of the blood which in turn excites the respiratory center. This, however, is not the whole story since in more severe types of exercise, with a continued increase in ventilation, the alveolar carbon dioxide tension may fall (Fig. 313). It may

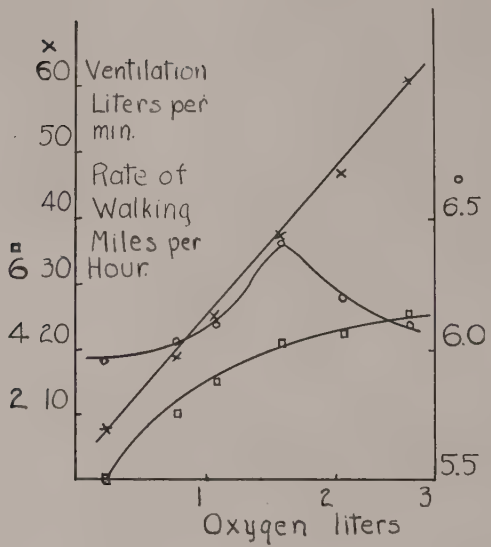

Fig. 313.—Relationship between oxygen consumption, total ventilation, and alveolar carbon dioxide during muscular work. Abscissa: oxygen consumption in liters per minute. Ordinates: *x*, total ventilation in liters per minute; *o*, alveolar carbon dioxide in per cent; □, rate of walking in miles per hour. (Drawn from data on page 29, Haldane: *Respiration*, Yale University Press, 1928.)

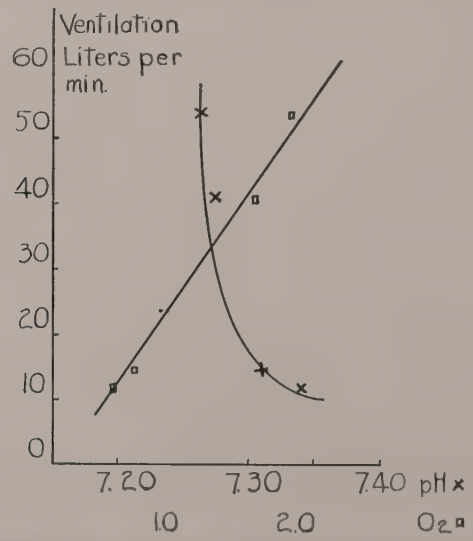

Fig. 314.—Relationship between pH, oxygen consumption, and total ventilation during muscular work. Abscissae: *x*, pH; □, oxygen consumption in liters per minute. Ordinate: total ventilation in liters per minute. (Drawn from Table 6, Arborelius and Liljestrand: Skandinav. Arch. f. Physiol. **44**: 215, 1923.)

then be assumed that at this point lactate is being produced and that the combined effect of lactate and carbon dioxide augments the respiratory effect. For more strenuous types of exercise, however, the proportionality between pH and total ventilation varies (Fig. 314). It appears that the respiratory center changes its sensitivity to chemical changes in the blood. More experimental work is needed before this remarkable agreement between total ventilation and the utilization of oxygen is explained satisfactorily (see page 604).

The maximal ability of the respiratory mechanisms to augment their activity to meet the demands of the body for obtaining oxygen and for ridding itself of carbon dioxide is another limiting factor in muscular work. The maximal limit for an average individual is about 80 liters of air per minute, although values as high as 113 liters have been reported (Robinson, Edwards, and Dill[601]).

CIRCULATORY CHANGES

With the augmented demand for oxygen by the active muscles, there is an increase in the amount of blood passing through these muscles. This increase in blood flow is produced by two things, an increase in cardiac output and a vasodilation of the capillary bed in the active muscles.

Cardiac Output.—Lindhard[588] has shown that during work the cardiac output varies with the metabolic rate. This is true when the same muscle groups carry out different intensities of work but does not hold when different groups of muscles are used. For example, Grollman[567] found that flexing the right thigh once per second raised the metabolism from 256 to 430 ml. of oxygen per minute and the cardiac output from 4.2 to 7.7 liters per minute, while flexing and extending the right forearm raised it to nearly the same value (453 ml.), although the cardiac output only reached 6.0 liters per minute. The differences are due to variations in the return of venous blood to the heart when different sets of muscles are used.

The increase in cardiac output during exercise is produced by (1) a more rapid heart rate and (2) a greater output per beat. Experimental data for these factors are given in Table C. The ability of the heart to pump blood

Table C

Relationship Between Cardiac Output, Heart Volume, Pulse Rate and Oxygen Consumption During and After Work (Liljestrand, Lysholm and Nylin[590])

CONDITION OF SUBJECT	AMOUNT OF WORK KG. METER PER MIN.	O_2 USED PER MIN. ML.	CARDIAC OUTPUT L. PER MIN.	PULSE RATE PER MIN.	OUTPUT PER BEAT ML.	HEART VOLUME ML.
Resting	----	312	3.2	56	57	670
Working	720	1557	9.7	131	78	650
Working	1260	2313	15.5	186	83	650
Recovery	----	398	4.8	80	62	635

is another important limiting factor in exercise. The maximal amount has not been determined because of the limitations of the methods for measuring cardiac output. Bazett (see page 403) has calculated, however, that in athletes a cardiac output as great as 27.5 liters per minute occurs during strenuous exercise.

Pulse Rate During Exercise.—It is a common experience that the heart beats more rapidly during muscular exercise. This phenomenon has been studied extensively by physiologists. A striking result of their study was the recognition of the rapidity of the increase; in fact, a shortening of diastole occurs during the first cardiac cycle following the commencement of muscular exertion (Buchanan;[546] Bowen[543]). Following the rapid initial increase, the

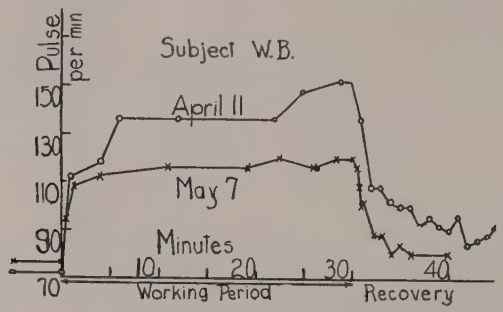

Fig. 315.—Pulse rates during work (bicycle riding) and recovery before and after training. (From Gemmill, Booth and Pocock: Am. J. Physiol. 92: 253, 1930.)

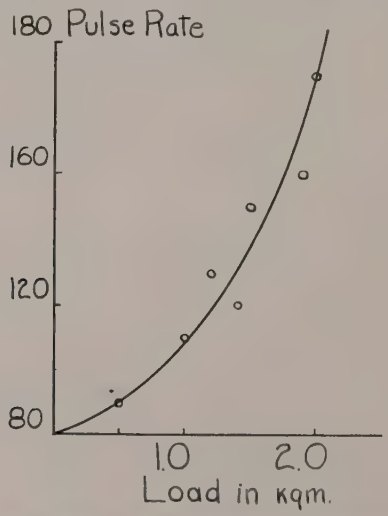

Fig. 316.—Relationship between pulse rate and load during muscular work in man. Abscissa: load in kilograms. Ordinate: pulse rate per minute. (Redrawn from Gillespie, Gilson and Murray: Heart 12: 1, 1926.)

heart rate gradually reaches a plateau. A typical curve showing these changes is given in Fig. 315. There are marked individual variations in the height of the rise. For example, Henderson, Haggart and Dolley[573] found that the pulse rates of athletes doing the same amount of muscular work varied from 126 to 152. In any one individual, however, there is a rough correlation between

pulse rate and the amount of work done[565] (Fig. 316). These authors also found that for the heavier loads the initial rise was much faster than for the lighter.

The return of the pulse rate to normal after exercise also occurs in two phases; a rapid drop is followed by a slow fall. Cotton and Dill[551] have observed that in the interval from ten to twenty seconds after exercise the pulse decreased at the rate of eleven beats per minute. Following this rapid drop, there is a slow return to the resting level. In fact, the postwork heart rate may remain above the prework level for one-half hour or more. Lythgoe and Pereira[591] have shown that the return of the heart rate to normal is slower than the recovery of the oxygen consumption.

Many physiological variables are involved in the explanation of these changes. Most authors agree that the primary rise is due to a reduction of vagal tone (Gasser and Meek;[562] Samaan[604]). Part of the secondary rise is due to the accelerator fibers of the sympathetic system. Complete removal of this system in dogs lessens the rise in rate by 30 to 40 per cent (Brouha, Cannon, and Dill[545]). It is interesting to note that the capacity for work of the sympathectomized dogs is not diminished. Another factor which must be considered is the presence of cardio-accelerator fibers in the vagal nerves. These fibers have been described by Jourdan and Nowak[581] as arising in the medulla and running down the vagi. Their endings are not affected by atropine and, of course, are not removed by sympathectomy. Their presence would explain the rise in pulse rate in the dog during exercise following removal of the sympathetic system and the injection of atropine. Brouha, Cannon, and Dill[545] concluded also that the cardiac acceleration was not due to the rise in body temperature, to muscular metabolites, to adrenalin, or to sympathin. Therefore, the factors which produce a rise in pulse rate during exercise are (1) a reduction of the tonic discharge of the cardio-inhibitor fibers of the vagi, (2) an increase in tonicity of the cardio-accelerator fibers in these nerves and (3) an increase in tonicity of the sympathetic accelerator fibers. Whether the same mechanisms work in all animals is not known; the conclusions given above apply only to the dog.

After exercise has started, the increased pumping action of the muscles and diaphragm increases the venous return. Hooker[578] found a definite rise in venous pressure in man during exercise. The increased venous return may evoke an acceleration of the heart rate, for in the anesthetized dog Bainbridge[538] found that the pulse rate increases reflexly following the injection of fluid into the veins (see page 469). The increased pressure at the junction of the great veins with the right auricle stimulates endings of afferent vagal fibers. The sensory impulses thus set up inhibit the tonic activity of the vagal cardio-inhibitory mechanism and, reciprocally, augment that of the sympathetic accelerator mechanism.

Systolic Output.—Not only does the rate of the heart increase, but also the amount of blood ejected at each contraction. Lindhard[588] reported changes of pulse rate from 66 to 90 during work, with an increase in the output per beat from 59 ml. to 100 ml. The increased venous return may dilate the heart and the cardiac muscle may respond to this with a greater force of contraction (Starling's law of the heart). Actual measurements have shown, however, that an increase in diastolic size occurs in only a few individuals (Meek and Eyster[594]). In other individuals, the systolic size changes with a decrease in the diastolic dimensions.

In these cases the increased stroke cannot be produced by change in the length of the cardiac fiber, but must be associated with a change in tension of the heart muscle.

Blood Pressure.—Two factors, increased rate and increased stroke volume, tend to raise the arterial blood pressure. Paterson[598] devised an apparatus to obtain systolic and diastolic blood pressures during work. The changes in systolic pressure found were proportional to the severity of the work, while the diastolic pressure showed only a slight increase (Table CI). The other main fac-

Table CI

Effect of Work on Arterial Blood Pressure and Pulse Rate (Paterson[598])

840 kg. per min.	182	98	150

tor affecting the blood pressure is the peripheral resistance. The vasodilatation which occurs in the active muscles will be described. In addition, it is thought that during exercise the splanchnic vessels constrict and so shunt more blood into the muscles. This idea is assumed from rather scant experimental evidence. The only direct observation on this subject has been made by Barcroft and Florey.[540] They followed in dogs the color changes in an exteriorized patch of colon and found that short bursts of running resulted in pallor. During longer periods of exercise, the color returned to the colon. In the same animals, the spleen contracted and remained in the contracted state during the exercise period. It is impossible to state whether or not the colonic mucosa and the spleen represent, so far as the present question is concerned, fair samples of the splanchnic area.

Essex, Herrick, Baldes, and Mann[558] have succeeded in measuring the blood pressure, the pulse rate and, in addition, the coronary and abdominal arterial blood flow in a normal dog during exercise—a remarkable achievement. They found that the coronary blood flow increases more than 300 per cent, but returns very quickly to the resting level after the exercise is stopped. The blood pressure and pulse rates show marked augmentation during work and rapid return to the normal during the recovery period. In a later paper Herrick, Grindlay, Baldes, and Mann[574] reported on the flow of blood in the abdominal arteries during work. They found that the blood flow in the common iliac artery is increased, but the flow in the superior mesenteric, renal, and splenic arteries is not changed. These experiments do not rule out the occurrence of vasoconstriction in the splanchnic area during exercise, for the increased peripheral resistance may be overcome by the general rise in blood pressure. The effect may be either no change in blood flow or an actual increase—the effect observed by these authors. Other factors which may influence the arterial blood pressure are the effect of the change in the pH of the blood on the vasomotor center and the effect of chemical and mechanical stimuli on the receptors of the aortic arch and the region of the carotid sinus (see Chapter XXXIII).

Blood Flow Through Active Muscles.—Muscles are richly supplied with capillaries for adequate blood flow during muscular work. The capillary distribution in muscle is illustrated in Fig. 317. Many experiments on the rate of blood flow through active muscles have been made with different types of apparatus. The earlier workers, using the Ludwig stromuhr (see page 432), described a decrease in blood flow through the muscle during tetanic contraction and an augmentation after the contraction was over. The later experiments of Verzar[607] supported this idea. This author used the direct method of measuring the blood flow by attaching a pipette to a vein and determining the time necessary for filling the pipette. Anrep,[535] using a hot wire aerotonometer, has substantiated the view of the earlier workers. In contrast are the work of Rein[600] and Millikan.[595] These observers using dissimilar techniques claim that blood flow is not hindered by muscular contraction; in fact, it may be augmented. The explanation of these two divergent viewpoints may be found in the experiments of Barcroft and Millen[539] who measured the temperature of the plantar flexors of the leg of man during rhythmic contraction of the leg muscles and during various degrees of static work. The leg

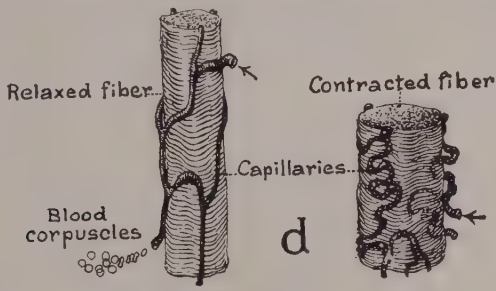

Fig. 317.—Relationship between muscle fiber and capillaries. (From Cullen and Brödel: Bull. Johns Hopkins Hosp. 61: 295, 1937.)

was subjected to external temperatures of 42° C. and 32.5° C., and at these temperatures the muscle temperature was 39.5° C. and 34.5° C., respectively. The assumption on which these experiments were done was that if the leg muscles cool on doing work at a high external temperature, or increase their internal temperature at the low external temperature, conclusion is that the flow of blood must be augmented. With this technique, these authors found that for rhythmic contraction and for low intensities of static work blood flow increased; for high degrees of static work, blood flow was impaired. These workers controlled their experiments by cutting off the circulation in order to get the magnitude of the temperature change that was due to muscular contraction itself. In the latter highly interesting experiments it was shown that with high intensities of muscular work, the amount and duration of work were not influenced by the absence of flowing blood. The discrepancies in the results obtained by the earlier workers are probably due to the differences in degree of the contraction employed by these observers. Therefore, we can accept the fact that light muscular work or rhythmic contraction increases the blood flow during the exercise and for some time afterward, but that heavy static work decreases or stops the blood flow during the exercise and only

increases it afterward. The fact that heavy static muscular work can be carried out without blood flow has also been demonstrated by Dolgin and Lehmann.[556] They determined the length of time that a man could hold a certain tension on a dynamometer with and without blood flow. For small tensions, the time decreased 59 per cent when blood flow was stopped; however, at higher tensions there was no difference in the duration, whether the blood flow was impeded or not. These results, with those of Bancroft and Millen, point directly to two types of metabolism in a muscle, the aerobic and anaerobic. Millikan's[595] experiments on the reduction of muscle hemoglobin show the same separation. Although during tetanic contraction the oxygen uptake is very rapid, the fact that the muscle hemoglobin is reduced with an intact blood flow demonstrates that the blood supply is unable to meet the oxidative demands of the muscle. Nevertheless, considerable tension may be developed and maintained under anaerobic conditions in man.

Vasomotor Control in Muscles During Contraction.—The increase in blood flow during and after work described in the previous section is due to three factors: dilatation of muscle capillaries, increase in arterial pressure, and the pumping action of the muscles themselves. Direct observations on the increase in the number of open capillaries in a muscle following contraction have been made by Krogh[582] and Ni[597] in frog's muscles. Ni found that in a resting muscle of a frog there were ten capillaries open per sq.mm. and that on stimulation the corresponding muscle on the other side showed 182 patent capillaries. Hartman and his associates[570] have studied the capillaries in the cat's sartorius muscle and have observed that faradic stimulation of the femoral nerve causes dilatation. In the gracilis muscle of the dog, Martin, Wooley and Miller[593] found 1,050 open capillaries per sq. mm. in the resting muscle, and 2,010 open capillaries in the exercised muscle. In a similar area there were 1,690 muscle fibers. Therefore, there is more than one open capillary per muscle fiber during exercise.

The opening of the capillaries may be due to neural and chemical influences. There are three ways in which vasodilatation in a muscle may be brought about by neural influences: by a decrease in vasoconstrictor tone or by an increase in vasodilator discharge, or by the concurrent operation of both of these factors. In normal animals, the decrease in vasoconstrictor tone is generally the most important factor, but activity of vasodilator fibers may play a role.

In sympathectomized cats, vasodilatation occurs when the animal struggles. This was interpreted by Pinkston, Partington and Rosenblueth[599] as being due to the discharge of impulses over dilator fibers in the dorsal spinal roots, but Bacq, Brouha and Heymans[537] state that the important factor under these conditions is the production of metabolites. The former authors claim a species difference, the change in blood pressure being not so marked in dogs, and the difference between cats and dogs being attributable to the more efficient vasodilator nerves of the cat. The role played by vasodilator fibers in the normal animal during muscular exercise has not been ascertained; and the exact pathways of the afferent stimuli to the vasomotor centers are not known. The importance of the carotid sinus mechanisms and the effect of direct stimulation of the vasomotor center by metabolites or by impulses from the higher centers are also in doubt. Nevertheless, there can be no doubt that neural mechanisms play an important part in the vasodilatation as they do in the increase in the heart rate during exercise.

Our knowledge of the mechanism of chemical control is not in any better experimental state than the neural. Gaskell, in 1877, showed that lactic acid

produces vasodilatation, and many others workers have demonstrated that a fall in pH produces the same effect. However, Ni[597] has shown that the capillaries dilate when iodoacetate is present in concentrations sufficient to block lactate production. Carbon dioxide also is a well-known vasodilator, and exerts the same effect as other acids which produce the same pH change. The amounts which have been used experimentally are far greater than those which are produced normally. Anrep[534] has stressed the production of a vasodilator substance, present in the venous blood, which has all the pharmacological properties of histamine. Adenylic acid has also been suggested as a possible chemical vasodilator. There can be no doubt that chemical substances, which may cause vasodilatation, may be produced during muscular contraction.

DIGESTIVE SYSTEM

Hellebrandt and Tapper[572] made a study of the influence of work on the secretory and motor functions of the stomach during exercise. They observed that the secretory response of the stomach to a test meal is inhibited and a fluoroscopic study of gastric motility revealed inhibition of gastric peristalsis. Since the motor inhibition was followed by increased activity the resultant of the two processes gave a normal emptying time of the stomach. Probably similar changes occur in intestinal motility and digestion.

CHAPTER LIX

THE REGULATION OF BODY TEMPERATURE

By Philip Bard

The classification of animals into two groups—warm-blooded (homoiothermic) and cold-blooded (poikilothermic)—according to their ability to maintain body temperature at a constant level, is more or less arbitrary. Between the two groups another exists, represented mainly by hibernating animals, in which at certain times of the year the animal is warm-blooded and at other times cold-blooded. The ability of the higher mammals to maintain a constant body temperature may or may not be present at the time of birth. The heat-regulating mechanism of the human infant, for example, remains ill developed for some time, so that exposure to cold is liable to lower the body temperature to a dangerous degree.

NORMAL VARIATIONS IN BODY TEMPERATURE

In animals in which the heat-regulating mechanism is fully developed, there is not, even during perfect health, entire constancy in temperature in the different parts of the body or in the same part at different periods of the day. The average rectal temperature of man is usually stated as being 37° C. (98.6° F.), but the normal diurnal variation may amount to 1° C. (1.8° F.), being highest (37.3° C., or 99.1° F.) in the late afternoon and lowest (36.3° C. or 97.3° F.) during the early morning hours. There are probably several causes for this variation, and they are in part at least dependent upon the greater metabolic activities of the waking hours and upon the taking of food. Apart from these influences, however, others which are less evident appear to operate; for it has been found that, when the daily program is reversed by night work, the usual diurnal variation, although much less pronounced, still remains evident even after this reversal in habit may have been kept up for years. It is of interest to note in this connection that nocturnal birds have their maximum temperature at night and their minimum during the day.

Regarding the temperature in different parts of the body, that of the rectum is usually about 1° C. higher than that of the mouth, which is again higher than that of the axilla. Of these three the mouth temperature is the most variable, for many conditions, such as mouth-breathing, talking, drinking cool liquids and even exposure to cold air, are sufficient to lower markedly the temperature of this region. Greater differences in the temperature of these different regions of the body are often observed in feeble individuals and in those with some circulatory disturbance.

It is not correct to state that the blood possesses an absolute thermal constancy. Venous blood from active muscles may be a degree or more above that from the skin, especially if the latter is losing heat rapidly. Doubtless the mixed venous blood of the venae cavae and right heart and the blood in the

central arteries exhibit a much greater constancy, but even here there may be some variations. The liver and other internal organs are normally several degrees warmer than the rectal cavity.

FACTORS WHICH MAINTAIN THE BODY TEMPERATURE RELATIVELY CONSTANT

The body temperature represents a balance between heat production and heat loss. The various factors which operate to achieve this balance are illustrated in a chart constructed by Du Bois (Fig. 318). At the bottom of this is represented a pair of scales one of which is weighted with heat production,

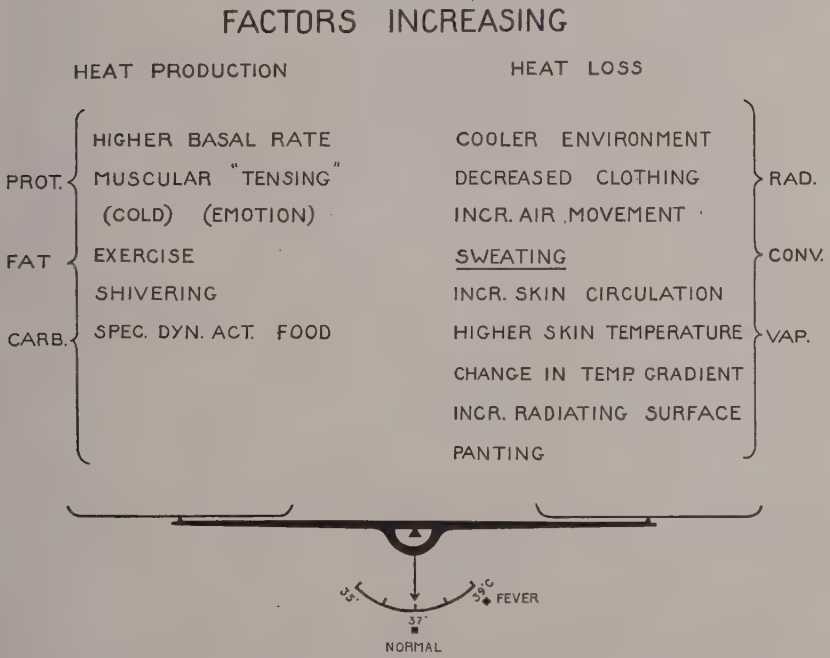

Fig. 318.—Diagram showing the more important factors which increase heat production on the one hand and heat loss on the other. Those which increase heat production do so through an increased metabolism of protein, fat, and carbohydrate in varying proportions. The factors which increase heat loss do so by increasing radiation, convection, and vaporization. The diagram of the balance indicates that heat production and heat loss are almost always in equilibrium, so that a normal body temperature is maintained at an average of 37° C. (From Du Bois: *Lane Medical Lectures: The Mechanism of Heat Loss and Temperature Regulation.* Stanford University Press, 1937.)

the other with heat loss. Normally the two pans are equally loaded and the pointer of the balance is at 37° C., which is the average normal temperature. As Du Bois[619] states: "Throughout the day there are slight changes in balance, as one factor or another predominates temporarily; but an adjustment made through the temperature-regulating center loads the opposite pan and brings the scale into equilibrium." This is the way in which all warm-blooded animals (birds and mammals) maintain a relatively constant temperature.

Changes in heat production which occur in the process of regulation constitute what is known as the *chemical* control, while alterations which modify the heat loss are spoken of as *physical* methods of control.

In his excellent account[627] of thermal adjustments in man and animals C. J. Martin points out that the mechanism of control is not like an ordinary thermostat which turns on and off the heat. A control of this sort could serve adequately only so long as the temperature of the body was well above that of its surroundings. Because of the fact that heat production cannot be reduced below a certain minimum, a simple thermostatic device would be unable to prevent a rise in body temperature when the environmental approached the body temperature. On the other hand, a regulating mechanism which functioned only by controlling the rate of heat loss would require a high consumption of fuel and would limit the range of environmental temperature compatible with a constant body temperature. As Martin puts it, the higher mammals and the birds have compromised and use both methods.

Regulation of Temperature by Altering Heat Production (Chemical Control).—This is effected by changes in the amount of combustion going on in the cells of the body. Heat production occurs mainly in the skeletal muscles where exothermic oxidative and nonoxidative reactions are constantly going on. When the activity of the muscles is abolished by curare, the temperature of the warm blooded animal immediately falls. Increased muscular activity, on the other hand, promptly raises the body temperature by 1° or 2° C. (Fig. 310). Normally a further rise does not occur, for the excess of heat is lost from the body through the operation of physical control. The temperature in such cases adjusts itself at a higher level where it remains fairly constant however strenuous the exercise. A certain amount of heat is also generated by the chemical processes occurring in the liver and other viscera, but when compared with the muscles this source is undoubtedly insignificant. The heart, of course, contributes some heat. It should be realized that all the mechanical energy liberated by the cardiac muscle is converted to heat within the body, for the energy of blood flow is spent in overcoming the frictional resistance of the blood vessels.

The production of heat goes on all the time in all tissues because of their resting energy requirements. In muscles the condition of tonic contraction present even at rest adds to this basal heat. When more heat is required by the body there may be an increase in tone, a "tensing" of the muscles, but this is not easily detected. Shivering, which is a special thermal response to a lowered environmental temperature, apparently consists of synchronous contractions in small groups of muscle fibers, repeated out of phase with those of other groups so that no extensive pull is exerted on the tendon. When more heat is required than can be obtained by this activity, the animal instinctively moves about in order that greater contractions may liberate more heat.

Heat is also set free by the specific dynamic action of the foodstuffs, and advantage may be taken of this to produce more heat when the cooling conditions are excessive; in winter, for example, there is an inclination to take more protein food, which has the highest specific dynamic action, than during summer. The per capita consumption of protein is said to be much greater in peoples living in temperate zones than in those living in the tropics.

It is well known that the metabolic rate is influenced by several glands of internal secretion. Of these the thyroid exerts the greatest direct influence on heat production. Complete thyroidectomy lowers the rate of combustion to a level about 40 per cent below normal, while the basal metabolism may be doubled in severe cases of hyperthyroidism. Thyroid activity is

apparently not subject to rapid changes, and there is thus little basis for supposing that the gland plays a part in the quick alterations in heat production which characterize most of the responses to environmental heat and cold. It may, however, be of some importance in certain slowly developing adaptations. For example, it is known that the thyroids of range cattle appear to be more active in winter than during the warm months of the year. The secretory activity of the thyroid is under the control of the anterior lobe of the pituitary which exerts its influence through the secretion into the blood of a thyrotropic hormone (see page 1030), but little is known of the circumstances which may modify the control. Recently, however, some light has been thrown on one aspect of this problem. Uotila[635] has obtained evidence that the increased secretion of thyrotropic hormone and the thyroid hypertrophy which normally occur in rats as a result of prolonged exposure to cold is prevented by previous section of the pituitary stalk. It is established that nerve fibers pass from the hypothalamus to the pituitary by way of the hypophysial stalk (see Chapter XVII) and these results suggest that normally long exposure to cold causes the production of increased amounts of thyrotropic hormone by provoking a discharge of nerve impulses over fibers belonging to the hypothalamico-hypophysial system (see page 192). It appears that the normal output of thyrotropic hormone is not dependent on the pituitary stalk; evidently it is determined by humoral rather than nervous influences. If there is a nervous control of the thyroid—the evidence on this point is slight and somewhat conflicting—it must be of minor significance in the regulation of body temperature.

The one endocrine organ whose activity is known to be subject to rapid changes induced through its nerve supply is the adrenal medulla. Furthermore, it is known that adrenalin has a calorigenic action in the body. These facts suggest that this gland may play a part in the processes of temperature control. As we shall see, there is evidence that it does, but consideration of this aspect of the subject will be postponed until we have reviewed the subject of physical control.

Regulation of Temperature by Altering Heat Loss (Physical Control).—Loss of heat from any body, animate or inanimate, can occur through conduction, radiation, convection, and vaporization. The amount of heat lost through these four channels depends chiefly on the surface area of the body and the difference between its temperature and that of the surroundings. For an understanding of the roles played by these methods of heat loss in the regulation of body temperature it is necessary to bear in mind certain facts of elementary physics.

Conduction.—This is a process in which heat is transferred through a solid, liquid, or gas from one molecule to another at a rate which depends on the thermal conductivity of the substance and the difference in temperature between the two points under consideration. The *heat conductivity* of a substance is the quantity of heat, measured in calories, transmitted per second from one face to the opposite face of a centimeter cube of the substance when the difference in temperature between the two faces is 1° C. The conductivities of certain substances are shown in Table CII. It is evident that many common materials and substances differ greatly in their capacities to transmit heat by conduction. Silver, as everyone who has stirred a hot liquid with a spoon made of this metal knows, is an excellent conductor. The great difference between brass and wood in this respect may easily be appreciated by placing one's hand momentarily first against a wooden door and then on the brass door handle or knocker. In doing this one may gain an erroneous conception of the temperatures of the two materials; although they are actually at the same tempera-

ture, the brass feels much cooler than the wood for the reason that being a much better conductor it abstracts heat very much more rapidly and so cools the skin very much more quickly. It should be noted that water is a relatively poor conductor. The fact that air stands near the bottom of the list is important physiologically. Thick hair, feathers, and clothes (especially woolen garments) serve to reduce loss of heat from the body not only because they are themselves poor conductors but also because they contain air in their meshes. A glance at Table CII explains why eiderdown, which is light and elastic, has been preferred by the luxurious as a material for beds and coverlets.

TABLE CII

HEAT CONDUCTIVITIES (COEFFICIENTS OF CONDUCTIVITY) OF VARIOUS SUBSTANCES (COMPILED FROM VARIOUS SOURCES)

SUBSTANCE	TEMPERATURE ° C.	CONDUCTIVITY
Pure silver	18	1.006
Brass	ordinary	0.225
Sandstone	ordinary	0.0055
Glass, soda	20	0.0017
Water	17	0.00131

Fir wood, across the grain	ordinary	0.00026
Air	0	0.0000568
Wool	ordinary	0.000054
Eiderdown	ordinary	0.000011

Radiation.—It will be recalled that radiant heat is transmitted by electromagnetic waves which like light waves are subject to interference, reflection, refraction, and polarization. Heat waves and light waves are identical except as regards wave length, and they all travel at the same velocity (about 186,300 miles a second). Radiation is the means by which enormous quantities of energy are transferred every day from the sun to the earth across the perfect vacuum of space. When radiant energy falls upon a body, energy of wave motion is transformed into heat. If the body absorbs 100 per cent of the radiant energy that falls on its surface, it is called a *perfect black-body*. Air is a very poor absorber of heat and therefore the radiant energy of the sun passes through the earth's atmosphere with relatively little loss, strikes the ground and is transformed into heat which warms the air by conduction and convection. The same principles apply to the situation in a room warmed by a stove; radiant energy from the stove does not to any extent directly heat the air in the room; it heats the walls (especially the opposite wall), tables, chairs, persons and other objects in the room because they absorb these electromagnetic waves emitted by the stove and in turn lose by conduction and convection (and if moist also by vaporization) some of the heat thus gained. Similarly, a person, as a result of the heat liberated by metabolic processes, radiates energy through the air to other objects. Du Bois[619] has clearly corrected a common misconception by stating: "It is a mistake to think that we radiate to the surrounding air; we radiate through the air to the solid objects in the vicinity. A man sitting in a heated room in the winter time loses a good deal of heat toward a cold window pane, and less heat towards the walls and ceiling. He receives radiant heat from the steam radiator." Of course when a number of people are crowded together they radiate toward one another and in this process each gains as much heat as he loses. Also, parts of one individual radiate to each other, e.g., the inner surfaces of the thighs, and so block each other off as far as loss of heat from the body is concerned. For this reason the effective radiating surface of a man is about 80-85 per cent of his total surface area.

The amount of radiation from an object is determined by several factors. It is proportional to the surface area of the body, to its emissive power and to the difference in temperature between the radiating body and the body to which it is radiating (actually to the difference between the fourth power of the absolute temperature of the radiating body and the fourth power of the absolute temperature of the object to which it is radiating).

The electromagnetic waves by which heat energy is transferred are of different lengths and lie within the scale of radiation which extends from the very short cosmic rays (0.0005

ångström) at one end to the very long radio waves (beyond 2.2×10^6 Å) at the other. As it reaches the earth the sun's radiation extends from the short ultraviolet (about 2,800 Å) to the near infrared (about 30,000 Å). The rediation from a red hot stove starts in the visible red (at about 6,500 Å) and ends in the far infrared. That from the human skin is distributed through the near infrared; it begins at a wave length of about 50,000 Å, reaches a peak in intensity at 90,000 Å, and extends to 200,000 Å (see Hardy[620]). Now it has been determined that the human skin, white or black, is a 97 per cent perfect blackbody.[620] At first thought it may seem hard to understand why there is no essential difference in this respect between the skin of a dark negro and that of a white man, but the following quotation from Du Bois[619] should clarify the matter: "The explanation lies in the fact man does all his radiating at wave lengths beyond the visible, and there is certainly no difference in color between a white man and a black man in a dark room in the middle of a moonless night."

Convection.—This form of heat transfer is limited to fluids and gases. It is simply a mechanical process of mixing in which a cooler fluid or gas comes in contact with warmer fluid or gas, becomes heated by conduction and carries heat elsewhere. Convection is the process whereby heat is carried up a chimney; the heated air rises because its density is less than that of cold air. Similarly, when a flame is applied to a beaker of water, the water eventually becomes equally heated all through because of convection; but first the water just over the flame becomes hot by conduction through the glass, then the colder water above displaces the hot water because it is heavier and finally mixing leads to an equal heating of all the water. In both these examples the mixing is automatic. On the other hand, the forcing of a current of cool air over a heated body cools that body by convection; such is the principle of the radiator of an automobile. When a man sits in a draft, the air near his skin, air which has been warmed by conduction, is replaced by cold air which in turn is warmed, and thus heat may be continually abstracted from the surface of his body. This process must be clearly distinguished from loss of heat by vaporization of water from the body surface, a process which is of course facilitated by movement of air. Because the specific heat of water (1.00) is so much greater than that of air (0.1692-0.2374), loss of heat by convection must be very great in the case of a man swimming in cold water.

Vaporization.—This process of heat transfer depends on the fact that it requires a definite amount of heat to change a given amount of any liquid into vapor without changing the temperature. For example, when water is boiling at one atmosphere it takes 539 small calories to evaporate one gram without changing the temperature of the water. This quantity is called the heat of vaporization of water. The change in water from a liquid to a gas involves the loss of heat from surrounding materials (including the liquid itself) and they are thereby cooled. Conversely, if a given amount of water condenses on an object it gives to the surroundings the same amount of heat which it took from them on vaporizing. In the case of the human body each gram of water vaporized from the surface at room temperature entails the loss of about 580 small calories and this is the figure which has been used in calorimetry experiments. The total amount of vaporization of water from a body depends on its surface area, the temperature of the surface and on the vapor tension and movement of the air. Liquids undergo evaporation at all temperatures, but the region over the free surface of the liquid may contain so much vapor that condensation occurs as rapidly as vapor is formed; when this is the case, the atmosphere over the liquid is said to be saturated. It must be remembered that as air is warmed its capacity to hold moisture is increased. Therefore on a very hot and humid day evaporation of sweat may still be an effective means of preventing a rise in body temperature. The ratio of the actual moisture content of a given volume of air to the maximum content possible at the same temperature is the *relative humidity*. It has been determined that a relative humidity of 40 to 60 per cent is desirable for comfort and health. When a body is at a temperature below that of its surroundings it can lose heat only by vaporization; it will at the same time of course be gaining some heat by the other means of thermal transfer.

Heat loss in man is effected mainly through the skin, but partly through the respiratory tract and lungs. The amount of heat lost through the feces and urine is such a small fraction of the total loss that it can be disregarded in all but the most accurate determinations. Through the skin heat is lost for the most part by radiation, convection, and vaporization of water. Through

the respiratory tract and lungs it is lost mainly by vaporization, but partly by convection as the inspired air is warmed; an increased ventilation augments the loss through the respiratory tract chiefly by increasing the vaporization.

In the case of human beings conduction is rarely an important means of heat loss. It occurs chiefly when a portion of the bare skin comes in contact with a good conductor, as when a boy after swimming sits on a cool stone in the shade. If a man lies on the cold ground in thin clothes some heat may be lost in this way. We voluntarily reduce heat loss by wearing clothes which, as already pointed out, are poor conductors and which trap in their meshes air which is an equally poor conductor.

It is obvious from what has been related that the proportions of heat lost from the body by the processes of radiation, convection, and vaporization are determined by the temperatures of the skin and the surroundings, by the movement of air over the skin and respiratory surfaces, and by the amount of water vapor in the air. The temperature of the skin of course depends on the rate at which blood passes through the cutaneous vessels. A brisk circulation here is essential for any considerable loss of heat by any of the three means of heat transfer just mentioned. On the basis of data compiled by Rubner and Aldrich, Martin states that of the total heat dissipated by a man, clothed and sitting in a room at 15° C., with the air 50 per cent saturated, about 44 per cent is lost by radiation, 31 per cent by convection, and 20 per cent by evaporation from skin and lungs. By means of measurements which involved the direct and accurate determination of the heat lost by radiation from the body surface Du Bois and his colleagues[619] have obtained similar figures. Hardy and Du Bois[621] determined with great accuracy that, in the case of a naked man lying quietly in a calorimeter where the temperature is 27.4° C. (a neutral temperature as regards basal metabolic rate) and the humidity 25 per cent, the loss of heat is distributed as follows: 58 per cent by radiation, 27 per cent by vaporization of water, and 15 per cent by convection.

Different conditions change not only the total amounts of heat produced and lost but also the proportions lost through the three different channels. For example (see Du Bois,[619] page 71), under basal conditions a normal man who was losing slightly more than 100 calories per hour was getting rid of 66 per cent of this heat by radiation; 15 per cent by convection and 19 per cent by vaporization of water. Then, when this same individual engaged in three vigorous games of squash rackets his heat loss increased more than fivefold, but the absolute amount of heat lost by radiation increased only slightly and a large increase in rectal temperature was prevented chiefly through increases in the losses by convection and vaporization, particularly the latter. Thus, at the end of the second game 12 per cent was being lost by radiation, 13 per cent by convection and 75 per cent by vaporization. Although the total heat lost was approximately five times that lost at rest under basal conditions, the heat production had risen even more, and this fact was reflected in a rise in rectal temperature from 37.6° to 38.8° C. At the same time there was a fall of nearly 2° C. in skin temperature, the result of the cooling effect of an enormous vaporization of the water produced by sweating. There was, therefore, a great cooling of the blood flowing in dilated vessels immediately below the surface of the body, but even this did not suffice to balance the augmented production of heat. The absolute increase in loss by convection was due to movements of the body in the course of the exercise.

Convection becomes a more important means of heat loss when moving air passes over the body surface or the body moves through still air. It is easy to understand how loss by convection increases when one sits in a draft or moves rapidly through air. But convection sometimes plays a more subtle role in heat loss. In 1918 Barr and Du Bois reported that a patient may lose more heat during a malarial chill when the skin is cold than in the period before the chill when the skin is warm. Of course a cold skin loses less heat by radiation and evaporation than a warm skin and the explanation of this rather surprising finding did not come until recently when the development of the Hardy radiometer made it possible to measure very accurately the amount of heat lost from the human body by radiation and so to separate the loss by convection which cannot be determined directly, but must be calculated by subtracting radiation and vaporization from total heat loss. It appears that the movements (shivering) which occur during a malarial chill may so increase the loss of heat by convection that the total loss from the cold skin may be equal to or even greater than that from a quiet warm skin. The effect of shivering is beautifully illustrated in an experiment described by Du Bois.[619] A naked subject entered a calorimeter where the air temperature was 22.7° C. He felt cold and his skin temperature dropped steadily (from 31.8° to 29.9° C.) during an initial period of nearly two hours. Then he began to shiver violently and during twenty-one minutes of this involuntary exercise his skin temperature rose only 0.5°-0.75° C. Now during the shivering period radiation was less than before but total heat loss was greater because convection was greatly increased on account of the movements; loss by convection was 29 per cent of the total as compared to 15 per cent during the period before shivering began. Interesting as these facts are, it must not be forgotten that with body movement far greater quantities of heat are lost by convection from a warm skin than from a cold skin and that shivering as a means of maintaining body temperature in the face of cold is not seriously counterbalanced by increased loss of heat through convection.

The Role of the Circulation in Physical Regulation.—Under average environmental conditions the main regulation of body temperature is effected by variations in the skin temperature brought about by cutaneous vasoconstriction and vasodilatation. These two processes, by altering the amount of blood flowing through the skin, decrease and increase the amount of heat lost by radiation, convection, and vaporization. The cutaneous blood flow is regulated not only by changes in arterioles, capillaries and veins, but also by the state of the arteriovenous anastomoses[615] which occur in large numbers in the extremities and are provided with innervated contractile cells. It appears that a very effective flushing of certain portions of the skin with blood can be achieved by the opening of these anastomoses. When cutaneous vasodilatation or vasoconstriction occurs in response to changes in environmental temperature it appears that an opposite change takes place in vessels of the interior of the body (see page 473) in order to maintain the capacity of the vascular system within reasonable bounds.

The marked sensitivity of the cutaneous blood supply to changes in the temperature of the environment has been pointed out (page 444). When the blood flow through the hand is examined in a person who has been exposed to the outside air, it may be little more than half that which it attains after he has been in a warm room for some time. In the outside air the vessels constrict to prevent heat loss by convection and radiation; in the warm room they dilate to facilitate this loss. The afferent impulses which reflexly control the change in the cutaneous blood circulation may be set up by local applications of heat or cold, as can be shown in hand-calorimeter experiments by applying a cold pad to the skin of the corresponding forearm, or allowing an electric fan to blow on the arm when an immediate curtailment of blood flow takes place. Or the reflex may be excited from distant skin areas, as illustrated in the curtailment in blood flow observed when the hand opposite to that on which the

observation is being made is placed in cold water. The magnitude of the change in the cutaneous circulation is more or less dependent upon the extent of the area of the body that is exposed to the change in temperature.

Vasomotor responses to temperature changes are greatest in the extremities which, of all parts of the body, are the most effective dissipators of heat. Burton[611] has shown that the blood flow through the human fingers can change over the enormous range of from 0.5 or 1.0 ml. to 80 or 90 ml. per minute per 100 ml. of tissue. In the hand the range is smaller, from 1 ml. to about 20 ml. (Freeman), and it is doubtless narrower in more proximal parts. The tremendous range of flow found in the extremities cannot possibly reflect a range in metabolic requirements, for in the case of the fingers, which contain little muscle, Burton calculated that the minimum value corresponds to the flow necessary to meet the oxygen demands of the skin; the range must represent a mechanism for temperature regulation by elimination of heat.

The Role of Vaporization in Physical Regulation.—When the loss of heat by radiation and convection is no longer adequate to prevent a rise in body temperature, or when these processes cannot operate effectively on account of a high environmental temperature, the necessary loss of heat from the skin is dependent upon the *evaporation of sweat.* A naked man lying quietly and surrounded by air at 34.5° C. is covered with sweat and his entire heat loss is by vaporization.[619, 622] Under ordinary or basal conditions, however, a man secretes little or no sweat; yet he vaporizes about 30 grams of water per hour and thus loses about 17.4 (30 × 0.58) large Calories. When individuals born without sweat glands are studied in a calorimeter under basal conditions it is found that they vaporize the same amount of water as do normal individuals. This evaporation of water constitutes the greater part of the weight loss which was first studied by Sanctorius in 1614 and which is termed the *insensible perspiration* (a very small part of which is due to the slight excess in the weight of the carbon dioxide eliminated over that of the oxygen absorbed). The water lost in the insensible perspiration comes partly from the respiratory surfaces, but chiefly from the skin. In the absence of any activity of the sweat glands the surface of the avascular epidermis is kept slightly moist by water which reaches it from the extravascular fluid supplied by the capillary loops of the dermal papillae. When the heat loss by vaporization must be increased, the sweat glands become active and water may collect on the surface of the body in large and obvious amounts. Provided the conditions of the environment are such that evaporation of water can readily take place (low relative humidity) the amount of cooling of the body that can be effected in this way is very great. A man may exist without any marked rise in body temperature in a very hot environment even when he is exposed to an outside temperature that is the same as that of his body, or even greater. To encourage evaporation, however, he should be naked or very lightly clad, and the air should be kept in constant motion so that the layers of air next to the skin, which ordinarily very quickly become saturated with vapor, are transferred and replaced by drier air. Movement of the air also increases the heat loss by convection, provided the temperature of the air is not too near that of the body.

The stimulus to increased sweating has been thought to be dependent mainly on changes in the temperature of the blood since sweating does not immediately set in when the body is subjected to heat, as by a warm bath or a hot pack. It usually takes from ten to twenty minutes after the person has

been placed in the bath or surrounded by the warm blankets of the pack before sweating becomes pronounced. It has been shown, however, that the body temperature does not always need to be raised before sweating sets in. In a hot bath, sweating starts on the forehead before there is any change in rectal temperature and if the hand be plunged in cold water the sweating stops at once.

Loss of heat by evaporation of sweat occurs only in certain animals. It is practically absent, for example, in the dog and cat, where sweat glands occur only on the pads of the feet. The degree to which it may occur also varies in different individuals of the same species. The power of withstanding high temperatures is proportional in man to the facility with which he perspires. Where sweating is interfered with by skin diseases—by ichthyosis, for example—exposure to heat or increased heat production, as by muscular activity, may raise the body temperature to a dangerous degree.

Another factor upon which the efficiency of evaporation of sweat in cooling the body depends is the relative humidity of the air. When this is high, evaporation of water into it cannot occur, and it is on this account that an increase in body temperature is much more likely to occur in warm, humid atmospheres than in those that are dry. At the same temperature people can live in perfect comfort in the dry air of the open plains, but suffer immediately from rise of temperature when they go into the humid air of the river valleys. Similarly, work in hot factories or in mines is quite possible at very high temperatures if the air is kept dry and in motion, but becomes impossible when the air is moist. In judging the adequacy of air from this point of view, it is therefore important to take not the ordinary dry-bulb thermometer reading but that of the wet-bulb.*

In animals like the dog, which do not sweat over the surface of the body, *vaporization of water into the expired air* is the most important method of heat loss. Animals with heavy coats of hair which interfere with loss of heat from the skin are especially dependent upon this process. When such an animal is exposed to warmth the breathing suddenly becomes much quicker but not deeper (polypnea), the mouth is opened and the tongue executes to-and-fro movements which are synchronous with the movements of the tidal air. Panting is large dead space overventilation and it is effective chiefly because there is a coincident stimulation of the salivary and buccal glands which yield sufficient water for the increased vaporization. The more rapid movements of air through the mouth and upper respiratory passages and over the tongue also facilitate cooling by increasing the conduction of heat from the mucous membranes of these parts. The importance of the mouth and pharynx in the loss of heat by these means is shown by the finding that after introduction of a tracheal cannula a dog cannot withstand an increase of external temperature nearly as well as a normal animal.

The Relative Importance of the Chemical and Physical Methods of Control of Body Temperature.—This was accurately studied in the dog by Rubner. Both methods come least into play when the environmental temperature is not far from that of the body. As the former falls, physical regulation will at first alone suffice to maintain the body temperature. When a lower level is reached chemical regulation will also come into play. This has been very clearly shown (Table CIII) in a short-haired dog by measuring the caloric output (by the indirect method) at various environmental temperatures. It can be seen

*The wet-bulb thermometer registers a temperature that is lower than that of the dry-bulb in inverse proportion to the relative humidity of the air. When the air is completely saturated with moisture, the temperature recorded by the two instruments will be the same; when it is perfectly dry, the difference will be maximal.

TABLE CIII

TEMPERATURE	CAL. PER KG.	
7.6	86.4	Chemical regulation
15.0	63.0	
20.0	55.9	Physical regulation
25.0	54.2	
30.0	56.2	
35.0	68.5	Rise in body temperature stimulating metabolism

(After Rubner.)

that no change in energy production occurred as the environmental temperature fell from 30° C. to 20° C., alteration of heat loss from the surface being sufficient—physical control—but that below 20° C. the metabolism became augmented—chemical control. At temperatures above 30° C. the metabolism also increased, because physical control was no longer adequate to prevent

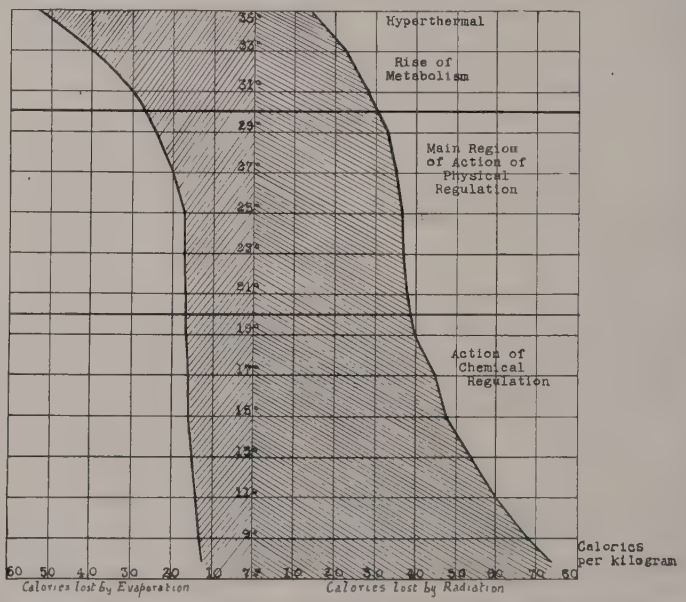

Fig. 319.—Rubner's chart showing the manner of heat loss at different room temperatures, in the dog. (From Lusk: *Science of Nutrition.*)

heating of the body and consequently an increase in all its chemical processes occurred. The temperature of 30° C. is hence styled the *critical temperature.* When the mechanism of physical control is upset in any way, chemical control sets in at a much higher temperature; for example, when the dog used in the above experiment had its fur shaved off, the caloric expenditure at 25° C. was 61.2 and at 20° C. it was 82.3. When there is a good layer of subcutaneous fat, the environmental temperature may be lowered considerably before chemical regulation sets in. Increased humidity at moderately high temperatures will increase metabolism because less heat loss can occur and the body becomes warmed.

These factors all play a role in determining the environmental temperature at which chemical regulation will become operative in man, but he has the advantage over other animals in that he can adjust his clothing to the environmental temperature. In studies[619] on a naked man in a calorimeter it has been found that when the environmental temperature lies between 22.7° and 34.5° C., the basal metabolism is surprisingly level and this fact suggests that the neutral range above and below which increased metabolism occurs may not be as narrow as is sometimes supposed. These experiments indicate that man has a very effective capacity to maintain a constant temperature over the range 23°-35° C., by adjusting heat loss alone.

The relative loss of heat caused by evaporation of water (in the expired air) and by radiation, etc. (from the skin) in the fasting dog is shown in Fig. 319, in which the abscissa gives the caloric losses by evaporation to the left and by radiation, etc., to the right of the vertical line about the middle of the chart, which also gives the environmental temperatures.

Baths also affect the energy output. They may induce a rise above the basal level not only when they are cold but also when they are very warm. This is shown in Table CIV.

TABLE CIV

	O_2 PER MIN. ML.	R.Q.
Normal	223.7	0.78
Hot bath at 42° C.	274.0	1.09
Normal	278.7	0.78
Cold bath at 17° C.	601.0	0.86

(Schapalo.)

The increase in the cold bath is, of course, due to chemical regulation of body temperature coming into play, whereas that in the hot bath is due to a warming of the tissues.

NERVOUS CONTROL OF BODY TEMPERATURE

The Part Played by the Innervation of Skeletal Muscle: "Thermal Muscular Tone" and Shivering.—Muscular activity is the main source of the heat produced by the body. In the discussion of the central nervous system it was emphasized that even at rest when no overt motion is taking place the muscles of the body are always exerting a certain small tension. This sustained activity or "tone" is due to low frequency discharges over motor fibers. It consists in a series of twitches or incomplete tetani in a certain fraction of the muscle fibers, but because the discharges in different motor neurons are asynchronous the muscle exerts a steady pull on its attachments. It is obvious that muscle tone is a continuous source of heat, and it has long been known that its abolition by curare or muscle denervation profoundly depresses the basal metabolic rate. We have seen how greatly muscular exercise increases heat production. But the central nervous system can make use of the great capacity of the skeletal musculature to produce heat without inducing locomotion or the other forms of overt bodily activity which we call muscular exercise. It does this by discharging impulses over motor fibers of the cerebrospinal system (not the autonomic system) in such a way that a tremor is produced. This activity

which we call *shivering* is specific in that it is evoked by exposure of the body to cold and on this basis may be differentiated from other forms of tremor.

The question has repeatedly been asked whether an increase in the tone of skeletal muscles, a response short of shivering, plays a part in the chemical regulation of body temperature. Burton and Bronk,[612] by studying the action currents of muscle, have secured some objective evidence of the occurrence of a true "thermal muscular tone." They found that in cats lowering of the body temperature below a critical level causes an increased muscular activity which precedes actual shivering and which, like ordinary muscle tone, is due to an incoordinated asynchronous twitching of the fibers of different motor units. This increased tone was found to begin with the first signs of a rise in metabolic rate. It was only later on continued cooling that this type of activity passed into the gross tremor of shivering which is brought about by the coordinated intermittent firing of motor units.

For years it has been held by one school of physiologists that increases in heat production in response to exposure to cold are due solely to increased muscular activity in the form of increased tone, shivering or actual exercise. The findings of Burton and Bronk are in harmony with this view. On the other hand, the two great pioneers in the field of metabolism, Voit and his pupil Rubner, held that some other factor or factors are involved in chemical regulation. We shall presently see that their surmise has received support in the shape of evidence that adrenalin, which has a calorigenic action, is secreted on exposure to cold. Already reference has been made (see page 865) to work which indicates that prolonged exposure to cold may lead to an augmented basal metabolism through increased thyroid activity.

The Part Played by the Autonomic Nervous System.—A consideration of the reactions which occur when the body temperature tends to rise or fall shows that with the exception of shivering "thermal muscular tone," alterations in respiratory movements and other responses in skeletal muscle all are mediated by the autonomic nervous system.

Only a few thermal responses are mediated by the parasympathetic division. Salivary secretion and secretion of the glands of the pharynx and respiratory tract, together with the local vasodilatation which accompanies this activity, are brought about by parasympathetic discharges. It is also possible that a small fraction of the cutaneous vasodilatation which occurs on exposure to heat is due to activity in this division of the autonomic. Doubtless some peripheral vasodilatation is mediated by impulses in dorsal root fibers, but, as we have seen (page 175), these are better classified as belonging to the cerebrospinal system than to the autonomic.

The greater part of the generalized thermal responses in visceral effectors is due to sympathetic control. Thus when environmental cold threatens to produce a fall in body temperature sympathetic activity leads to constriction of peripheral vessels, erection of hair (of feathers in birds) and liberation of adrenalin. The pilomotor activity serves to enmesh near the skin a layer of poorly conducting air; in the human being this response is signalled by the appearance of "goose flesh," a change signifying the survival of a reaction which was useful before the processes of evolution did away with most of man's body hair. The secretion of adrenalin is of service because of the thermogenic action of this hormone. Among the bodily responses to heat are sweating and

cutaneous vasodilatation. The former is due to impulses in cholinergic postganglionic sympathetic fibers, while the latter is to a very considerable extent accomplished by inhibition of the tonic discharge of impulses over sympathetic vasoconstrictor fibers. The contribution of specific sympathetic vasodilators to this response is possible.

The very great importance of the sympathetic system in the regulation of body temperature has been demonstrated conclusively by the study of animals in which total removal of the sympathetic chains has excluded all possibility of impulses reaching effectors over neurons of this system. As pointed out in Chapter XVI sympathectomized cats and monkeys remain in good health and show no abnormalities unless they are subjected to conditions of physiological stress. When such animals were first prepared and studied by Cannon and his collaborators[613] it was noted that they showed certain defects when confronted with the problem of maintaining a normal temperature in the face of environmental heat and cold. The sympathectomized cats "exhibited a marked antipathy to cold air and drafts. It has not been uncommon to see them literally spend days during the colder periods of the winter crouched on top of the warm-water heater and descending from it only at feeding times." In this they stood in marked contrast to the normal cats with which they were housed. When placed in a cold room the sympathectomized cats showed, in comparison with normal cats, a deeper depression of rectal temperature and a much greater frequency and prominence of shivering. Indeed, in such animals shivering appears to be the chief, if not the only, protection against a fall in temperature.

A study of the effect of high and low environmental temperatures on sympathectomized animals was later carried out in Cannon's laboratory by Sawyer and Schlossberg.[633] Table CV is from their report, and shows in a convincing manner the deficiencies of the animals without sympathetic pathways to visceral effectors. When normal cats are placed in a cold room at 8°-9° C. for three to four hours they exhibit occasional spasmodic shivering, show some erection of hair, and their rectal temperature usually rises slightly in evidence of an efficient control. Sympathectomized cats, on the other hand, behave quite differently. In them shivering begins at once and continues without interruption, but in spite of this powerful thermogenic response rectal temperature invariably falls. There is no erection of hair, and peripheral vessels fail to contract to the normal extent. Sympathectomized animals are also deficient in their response to environmental heat. Sawyer and Schlossberg found that normal cats placed in a hot room at 40°-41° C. for periods of from one to two and a half hours showed an average rise in rectal temperature of 1.40° C., while sympathectomized cats experienced an average rise of 2.25° C. The overt responses, such as panting and salivation, were more marked in the latter animals.

It has already been pointed out that the adrenal medulla is an integral part of the sympathetic system. Under ordinary quiet conditions of existence the secretory activity of this gland is at a standstill (page 171). Adrenalin is produced when conditions of stress cause a widespread and vigorous discharge of sympathetic impulses. Added to the blood as a result of a discharge of preganglionic sympathetic impulses, it supplements the action of postganglionic impulses throughout the body, but we know that this hormone exerts two effects

which apparently cannot be induced by the nerve impulses. These are increased tissue oxidations and the acceleration of the process whereby liver glycogen is converted to blood sugar. Both, more especially the former, are of importance in temperature regulation. The role of medulliadrenal secretion in the chemical control of body temperature was demonstrated by Cannon, Querido, Britton and Bright.[614] Surviving healthy cats in which the heart had

*Cat developed snuffles next day.

been denervated showed marked accelerations of the pulse rate when exposed to cold. The same phenomenon occurred when a heat debt was established by introducing a known amount of cold water into the stomach. After removal of one adrenal gland and denervation of the other the same procedures caused either slight accelerations, no change, or a moderate decrease in heart rate. As a result of these experiments it was concluded that an increased discharge of adrenalin occurs under circumstances which tend to lower body temperature. The evidence that secreted adrenalin is of service under these

conditions by virtue of its calorigenic action rests on the observation that when the adrenals are inactivated by denervation shivering becomes much more prominent. A moderate heat debt may be met successfully by a normal animal without shivering, but after adrenal inactivation the establishment of the same debt results in prompt and long-continued shivering. Cannon and his collaborators also studied the effects of a heat debt on a number of human subjects. It was found that debts averaging 449 small calories produced a rise in oxygen consumption which averaged 16.4 per cent. Since these increases were not accompanied by shivering, it was inferred that they were due to some factor other than muscular activity, presumably stimulation of metabolism by adrenalin. It is possible, however, that an imperceptible increase in the tonic contractions of skeletal muscle occurred. In any event, the animal experiments show clearly that when adrenalin is discharged on exposure to cold shivering is less marked. It is hard to avoid the conclusion that, by virtue of its calorigenic effect, secreted adrenalin is a real factor in the control of body temperature.

The Central Nervous Control of Body Temperature.—All the changes in the body which normally act in the face of changes in environmental temperature to preserve a relatively constant temperature are due to an increased or decreased number of impulses in cerebrospinal and autonomic nerves. Since these alterations in impulse discharge are of central origin we must search in the central nervous system for the mechanisms which execute the delicate control outlined in the preceding paragraphs of this chapter.

In the case of man the body temperature is to a considerable extent under voluntary control. By the choice of clothing and the artificial heating and cooling of habitations we supplement the involuntary management of heat loss. Similarly, we may aid the chemical control of body temperature by voluntarily increasing or decreasing our muscular activities. It is, of course, most fortunate that we do not have to rely entirely on voluntary adjustments to secure and maintain the necessary thermal environment for our body cells. Were that the case, it is obvious that little time or strength would be left for any other endeavor. The essence of the matter is that if the processes of phylogeny had failed to develop an automatic thermotactic device in the central nervous system of birds and mammals, these animals could never have attained that freedom from environmental influences which distinguishes them from the cold-blooded amphibian and reptile.

When the spinal cord is transected in the cervical region, body temperature quickly falls unless it is artificially maintained. The extent to which the animal or man comes to behave as if cold-blooded, after cord section, varies somewhat with the level at which the cut is made. If it is in the upper thoracic region, for example, the regulation against cold, although distinctly less efficient than normal, is far better than when the secton is made through the cervical cord. The difference is largely dependent on the fact that after the lower section much larger muscle groups and skin areas are left innervated from the brain, but preservation of the cerebral connections of the uppermost portion of the sympathetic outflow is also a factor.

In dogs long surviving spinal transection and entirely free from symptoms of spinal shock Sherrington[634] showed that there is in the region innervated from behind the lesion marked failure of vasomotor responses to even great changes in environmental temperature. Shivering does not occur as a spinal reflex no matter how considerable the exposure to cold, and Sherrington was unable to induce sweating to heat in the paraplegic regions of his dogs.

The dependence of normal thermal responses on prespinal central mechanisms is strikingly illustrated by the appearance of shivering in the muscles innervated anterior to the level of a spinal section when the parts below are immersed in cold water. Sherrington found that "the nonappearance of cold shivering in the paraplegic region of the dog can reveal with great clearness the exact segmental level of the spinal lesion by demarcating the muscle-field innervated behind the lesion from that in front. The boundary so shown will actually subdivide an individual muscle, e.g., the anterior part of deltoid will shiver violently while in its posterior part no shivering can be evoked." If the transection is at or above the 7th cervical segment and the room temperature is kept at its usual level, the shivering in the anterior parts of the body is not accompanied by any signs of cutaneous vasoconstriction. The forefeet and ears remain warm to the touch because of the separation of the sympathetic outflow from prespinal centers. With a midthoracic transection the response to cooling the hindparts includes vasoconstriction. These reactions in regions not directly exposed to environmental cold and yet separated from the cooled parts by cord transection may be reflexes evoked from the sentient parts by cold blood from the chilled region or they may be the results of a direct effect of cooled blood on the thermotactic mechanisms of the brain. The operation of the latter possibility is rendered plausible by the observation that localized cooling of the brain stem causes shivering and vasoconstriction (Barbour[609]).

Certain investigators have claimed that after complete low cervical transection of the cord various experimental animals and even man may show a considerable capacity to regulate body temperature (for an excellent critical review of this subject see Ranson[631]). Recently G. Clark[616] has reported the results of a careful study of cats which were maintained in excellent health for long periods after complete section of the lower cervical cord. While confirming the results obtained by Sherrington *(vide supra)* he has been able to throw light upon some of the claims to which allusion has just been made. Clark found that after his cats had been subjected for weeks at a time to a relatively low environmental temperature (about 70° F.) they were able to maintain a higher body temperature on exposure to cold than before this treatment. He concludes that while such preparations are "unable to make the adjustments necessary for maintaining a normal body temperature when there occurs a sudden and considerable fall in environmental temperature" they may develop a slow adjustment to cold, an acclimatization. Since this change is not accompanied by any capacity to shiver in muscles innervated from below the transection or to vasoconstrict or erect hair in any region of the body, and since no signs of chronic vasoconstriction were evident, Clark suggests that the animals develop, as a result of exposure to low temperatures, an increase in the basal metabolic rate. He finds that the greater ability to withstand cold is lost if the animals are kept again in a warm environment. Ranson[631] has suggested that this slow and very limited temperature regulation which is evidently humoral in origin may be referred to increased thyroid activity. In the light of Uotila's results (see page 865) it would be interesting to know whether it depends on the integrity of the pituitary stalk.

Studies on spinal animals show conclusively that *the essential heat regulating machinery of the central nervous system has a prespinal localization.* It remains to consider the delimitation or distribution of this. That the decerebrate cat or dog is essentially poikilothermic is a fact universally admitted. Even when such preparations are kept alive for several weeks, as in the experiments of Bazett and Penfield (see page 136), they display no effective thermoregulatory responses. After any mesencephalic transection of the brain in carnivores shivering cannot be induced by cooling either the skin or the entire body, and the only respiratory response to heating is a slow increase in the

rate of breathing from a normal frequency of 16-40 a minute to 90 or less. True panting in the sense of to-and-fro movements of the tongue and labial commissures with mouth open and at a rate of 200-375 a minute is never seen. The heat-regulating center or centers of the higher mammals must reside somewhere above the midbrain, i.e., in the diencephalon, corpora striata, or cerebral cortex.

The literature on the subject of temperature control which appeared before the year 1912 is filled with assertions that the corpora striata are essentially concerned in this function. But most of the experimental evidence put forward in support of this contention was open to various interpretations and signified little; the work consisted chiefly in making mechanical or chemical injuries in the striata and noting transient hyperthermias. At the end of this period Barbour[609] made the significant discovery that in the rabbit cooling or heating the region of the corpora striata induces marked thermal responses: heating produces faster breathing and vasodilatation, while cooling gives generalized vasoconstriction in the skin and shivering with an increase in oxygen consumption. In the light of subsequent work it seems certain that Barbour's results were due to alterations in the temperature of the *hypothalamus,* which of course lies at no great distance from the corpora striata. As we shall see, this ventral division of the diencephalon is without question the part of the brain most essential for temperature regulation.

Ott in 1887 first placed emphasis on the hypothalamus as a region of the brain concerned in temperature control, but his observations had little influence on contemporary workers. It was in 1912 that Isenschmid and Krehl,[623] working on rabbits, first furnished acceptable evidence that after removal of the cerebral cortex and corpora striata an animal retains a nearly normal ability to regulate its body temperature throughout a wide range of environmental temperatures. Since rabbits in which all the brain down to the mesencephalon had been removed were found to possess no ability to regulate, it was concluded that the diencephalon contains the temperature regulating center. Other experiments, which were continued by Isenschmid and Schnitzler,[624] indicated that in the rabbit the tuberal region is the essential portion of the diencephalon, as far as temperature regulation is concerned (see Chapter XVII). Much later other investigators (Keller and Hare,[625] Bazett, Alpers and Erb,[610] and especially Ranson and his collaborators[631, 632]) showed conclusively that the hypothalamus is the one part of the brain which is absolutely essential for normal temperature control. There is evidence that with the exception of certain parts of the cerebral cortex no portion of the brain lying above the hypothalamus plays any important role in temperature regulation. Pinkston, Bard and Rioch[630] studied the responses to changes in environmental temperature in a number of long-surviving cats and dogs which had been deprived of neocortex and additional portions of the forebrain. It was found that animals lacking cortex, striatum, and all of the diencephalon except the hypothalamus and the most medial portion of the thalamus regulate in the face of extremes of cold and heat just as efficiently as do animals which are merely decorticate. Moreover, these animals showed only relatively minor disturbances of temperature regulation when compared with normal controls. On the basis of functional tests and histological studies of serial sections of the brains, it was concluded that in the decorticate animal the striatum, the lateral basal olfactory areas and pos-

sibly the rostral two-thirds of the midline groups of thalamic nuclei play no significant role in temperature regulation.

The evidence that the hypothalamus contains the most important central mechanisms for temperature regulation has been very considerably strengthened and extended by Ranson and his collaborators (see Ranson and Magoun[632] and Ranson[631]). The general conclusion has been reached that there are two rather distinct and anatomically separate thermo-regulatory mechanisms in the hypothalamus, a rostrally situated one which prevents overheating and a more caudally located mechanism which protects the body against chilling. By placing well-circumscribed electrolytic lesions in different parts of the brain stems of cats and monkeys Ranson and his associates have demonstrated that injuries limited to the caudal portion of the hypothalamus (bilateral lesions dorsolateral to the mammillary bodies), which leave the rest of the brain intact, produce a permanently poikilothermic condition. Although ordinary motor activity is not impaired, the animals fail to sweat or pant when warmed and do not shiver when cooled. On the other hand, when the tissue lying above and in front of the optic chiasm and below the anterior commissure (the preoptic and supraoptic regions—see Fig. 69, page 188) is destroyed the animal is no longer able to protect itself from overheating—on exposure to warmth a cat with such a lesion fails to pant or sweat and consequently develops a hyperthermia—but it shows little or no impairment of its capacity to regulate against environmental cold. Further evidence that this rostral portion of the hypothalamus is prepotent in bringing about heat loss was secured by Magoun, Harrison, Brobeck and Ranson[626] who examined the effects of locally heating various parts of the hypothalamus by passing a high frequency alternating current of low voltage between the tips of two electrodes inserted into the brain; such a current warms but does not electrically stimulate the tissue through which it passes. It was found that panting and sweating could be far more readily obtained by warming the area between chiasm and anterior commissure than any other part of the hypothalamus. The study of the effects of lesions showed that the descending pathways through which this mechanism for heat loss acts run backward through the lateral hypothalamic areas (see Fig. 69, page 188).

As already intimated the hypothalamic mechanisms which protect the body against environmental cold by causing heat formation (e.g., by shivering) and inducing heat conservation (by vasoconstriction) are to a considerable extent separate from those involved in regulation against heat. On the whole they lie more caudally. They are not seriously impaired by hypothalamic lesions of moderate size unless these are bilateral and located in the caudal part of the lateral hypothalamic area so as to destroy much of the tissue between the mammillary bodies and the cerebral peduncles. Ranson[631] has concluded that the neurons which constitute the chief central mechanism for protection against cooling are "distributed through a large part of the hypothalamus and are perhaps in part at least identical with those which are responsible for vasoconstriction and piloerection and some other sympathetic functions." The fact that stimulation of the hypothalamus evokes a widespread sympathetic discharge was mentioned in Chapter XVII. And there it was pointed out that the significance of this experimental finding probably lies in the fact that general bodily functions which involve sympathetic activity, functions such as

temperature regulation and the expression of certain forms of emotional excitement, rather than the sympathetic system itself, are integrated at the hypothalamic level.

Although there can be no doubt about the indispensability of the hypothalamus for temperature control, it would be a mistake to conclude that it contains the only neural mechanism concerned in this regulatory function. The hypothalamus must exert its effects through the autonomic and somatic centers of bulb and cord. There is also evidence showing that cortical mechanisms are concerned in temperature regulation. It is well known that vasomotor changes are induced by stimulation or ablation of cortical tissue (see page 186). Removal of the frontal pole of one cortex in the dog produces in the contralateral side of the body chronic cutaneous vasodilatation with failure of the skin vessels to constrict normally on exposure to cold.[630] In the monkey a comparable lesion causes vasoconstriction (Kennard).

Complete decortication in carnivores (cats and dogs) does not seriously impair temperature regulation, but the results observed by Pinkston, Bard and Rioch[630] in long surviving animals show that this part of the brain exerts some influence on the processes of temperature control. In addition to the vasomotor effects just mentioned dogs without neocortex and with subsequent secondary degeneration of the thalamus showed the following changes in their thermal responses: a very delayed slow hyperpnea in response to conditions that promptly induced true panting in the same animals before operation; a rise in rectal temperature before hyperpnea developed (normal dogs show polypnea without any rise in rectal temperature); and immediate vigorous shivering in response to cold, frequently producing a rise in body temperature, whereas before operation the same animals showed the usual delayed and less marked reaction with a fall in body temperature. Cats with equivalent lesions behaved in a similar manner, but showed no disturbance of the panting response, which in this species is not as highly developed as in dogs. It should be emphasized that all these animals, whether lacking only cortex or deprived of practically all cerebral tissue above the hypothalamus, maintained normal body temperatures under ordinary laboratory conditions and withstood exposure to heat (37.5° to 41.4° C.) and cold (15.0° to 0.6° C.) for as long as four hours with relatively small changes. The disturbances they showed were in the details of regulation, and some were overreactions (e.g., excessive shivering). Whether the cerebral cortex exerts its influence through the hypothalamus or directly on bulbospinal centers is not known. Finally, we may be sure that in man, where the general process of corticalization of function has reached its fullest expression, the cerebral cortex exerts a very much greater influence on temperature regulation than in the lower mammals which, of necessity, have been the subjects of experimentation in this field of neurophysiology. There are, however, a number of clinical studies (see Davison and Selby,[618] and Davison[617]) which indicate the importance of the hypothalamus in the regulation of temperature in man.

The processes of temperature control may be set into action in one or both of two ways. Reflex responses are evoked by the effect of heat or cold on receptors. The best known examples of this are the vascular changes which occur in unexposed skin areas the moment another area is heated or cooled. Normally panting in the dog is this type of response. A dog will pant on slight cutaneous warming, and without the slightest rise in rectal temperature. Indeed he may continue to pant when the response has caused rectal temperature to drop below normal, provided the skin is locally warmed. This was designated

"reflex panting" by Richet, who discovered its nature. It does not occur in dogs under anesthesia. "Central panting," on the other hand, is a form of the response which Richet considered to be the result of warming of the nervous centers in the brain by heated blood. It is seen in anesthetized dogs, and a rise in rectal temperature is required for its occurrence. The observation that panting may be evoked by warming the carotid blood or by direct application of heat to the rostral hypothalamus (see above) indicates the correctness of Richet's view as to its nature. Doubtless all thermal responses could be classified as reflex or central or both. Panting in the cat is always "central" in the sense that it never occurs normally unless there is a rise in rectal temperature.

Fever

The clinical application of a knowledge of the mechanism of heat regulation in the animal body concerns the causes of fever. Recently the artificial production of fever for therapeutic purposes has added still further to the clinician's interest in the subject. In its most familiar form fever is produced by infectious processes, but it may also be due to various other causes, among which may be mentioned the parenteral injection of foreign protein, excessive destruction of protein substances in the body itself, the action of certain drugs, and lastly, injury to various portions of the brain. Several types of fever are recognized: when the temperature remains constantly above the normal, it is known as continuous fever; when oscillations occur but the temperature never falls to the normal level, it is known as remittent; when it attains the normal level at certain periods during the day, it is known as intermittent.

The Mechanism of Fever.—During a *sudden rise* in body temperature there is, on the one hand, increased heat production in the muscles, and on the other, diminished heat loss from the surface of the body. *The fever is therefore due to an exaggeration of the processes by which the body normally reacts to conditions which tend to lower the body temperature.* Shivering may occur, and the constriction of the cutaneous blood vessels produces the subjective sensation of chills, causing the skin to become pale and cold to the touch. The skin muscles also contract, producing "goose skin." During this stage, objective demonstration of the curtailment of the skin circulation becomes possible by observation of the blood flow through the hands and feet. When the temperature *suddenly falls* again (the crisis, as it is called), the muscles become flaccid and produce less heat, and the cutaneous blood vessels dilate, as can also be shown by measurements of the blood flow of the hands and feet. At the same time also, the sweat glands are stimulated and marked perspiration occurs.

Concerning *the cause of continuous fever,* it must be assumed that the balance between heat production and heat loss has been adjusted at a higher plane than normal. We cannot explain the fever on the basis either that heat production alone is increased or that heat loss alone is diminished, for in neither of these cases would the temperature stand at a permanent level. The thermoregulatory nerve centers, while set at a higher plane in fever, are still capable of responding in the usual way to the influences which cause the body temperature to change in a normal person. For example, when a fever patient is subjected to a hot bath so that his body temperature rises about 0.2° to 0.5° C., sweating occurs just as in a normal individual; or if exercise is taken the increased amount of heat thereby produced in the muscles is dissipated in the usual way. When, on the other hand, the patient is exposed to cold, the vessels of the skin contract and he shivers.

Although fever is not caused by an actual disturbance of the balance between heat production and heat loss, neither of these processes is proceeding at its normal rate. That there is a distinct increase in the total heat production of the body in acute fevers in well-developed persons has been shown by means of the respiration calorimeter. This increased heat production is not observed in patients who have been brought into a weakened condition and in whom the muscular tissues have become atrophied by long-continued fever.

It is particularly during the chill preceding a fever that the basal metabolism is increased. At the onset of an attack, in malaria for example, the caloric expenditure may be increased two or three times over the normal. This is related to the shivering, for it occurs also when this is brought on by a cold bath which may cause it to increase 180 per cent. During the continuous fever, of typhoid for example, the increased metabolism is proportional to the rise in rectal temperature and in a general way van't Hoff's law holds, namely, that the chemical activities (metabolism) of the body increase from two to three times for every rise of 10° C. in rectal temperature. This means that the caloric output increases by about 7 per cent for each degree Fahrenheit through which the rectal temperature is raised. These relationships are also evident in the fever which follows intravenous injection of proteose or typhoid vaccine. The increased heat production in continuous fever is mainly dependent upon the increase in body temperature and is not one of its causes, as is evident from the fact that far larger quantities of heat are frequently produced in normal individuals as a result of muscular exercise or the taking of large quantities of protein-rich food. The heat thus produced is, however, very quickly dissipated, so that only a temporary rise in temperature occurs. A large heat production also occurs in hyperthyroidism without a corresponding rise in body temperature.

Similarly, it can be shown that in continuous fever there is a relative inefficiency in the mechanism of heat dissipation. When the temperature of a normal person is artificially raised through about 1° C., a marked increase in cutaneous blood flow and profuse perspiration are invariably noted. In a patient with fever of the same degree, on the other hand, there is practically no change in the skin circulation; indeed, it is usually diminished, and there is no unusual perspiration. The heat-regulating mechanism is now fixed on a plane that is higher than the normal, so that although further increase in body temperature, as we have seen, calls forth responses like those in a normal individual, yet at the fever temperature itself there are none of the reactions which a normal individual would exhibit if his temperature were artificially raised to that level.

The adjustment of the temperature at the higher level is by no means so perfect as it is at the normal level of health, so that a normal subject is more resistant to the effects of cold than is a patient with fever. The degree of response of the fever patient, however, varies considerably from time to time; a cold bath in typhoid fever, for example, lowers the body temperature much less effectively at an early stage in the disease, when the fever is more or less continuous, than later when it is becoming of the intermittent type. In the third week of the disease the cold bath more readily brings down the temperature and keeps it down for a longer time than during the first or second week. The mechanism for heat loss is also deranged in fever, which explains the rise in tem-

perature that is likely to follow the performance of even moderate muscular exercise or the taking of too hearty a meal in tuberculous or convalescent typhoid patients.

Changes in the Body During Fever.—In seeking the cause of fever which is evidently of an obscure nature, it is necessary to collect all the information we can regarding the metabolic changes that are then occurring in the animal body. A few of the most significant facts that have so far been collected may be mentioned here. Some of the most important concern the disturbance in nitrogenous equilibrium caused by the considerable loss of nitrogen which takes place in fever patients when they are fed on the usual hospital diet prescribed for such cases. This loss of nitrogen is no doubt the result of the partial starvation in which the patient is kept; for it has been shown that patients with typhoid fever may be maintained in nitrogenous equilibrium by feeding them with relatively large amounts of carbohydrate, which acts by protecting the protein of the body from disintegration. The protein minimum to which fever patients can be reduced is nevertheless considerably higher than the minimum in normal individuals.

From the above results as a whole, it is probably safe to conclude that there is *a specific destruction of protein* going on in the body during fever. Further evidence of such a destruction is furnished by the presence in the urine of excessive amounts of creatinin, of purine bases, and, it is said, of incompletely hydrolyzed proteins, such as the albumoses (proteoses). Moreover, when the fever suddenly terminates in crisis, there is a marked increase in the excretion of urea (the epicritical urea increase), which indicates that an extensive deamination of protein building stones (amino acids) is occurring. The so-called "diazo reaction" obtained in the urine during the fever is also believed to depend on the presence of abnormal protein-disintegration products. As to the specific cause of the increased protein disintegration, little is known.

Although there is increased protein breakdown during fever, it must not be forgotten that when food is refused only about 20 per cent of the total expenditure of the body is derived from this foodstuff, 80 per cent coming from non-nitrogenous material, which must be fat, because the available carbohydrates are used up at an early stage.

Since the general metabolism is increased, the excessive breakdown of the fatty substances, occurring as it does in the presence of a diminished combustion of carbohydrates, interferes with the proper oxidation of the fatty-acid molecules and leads to the appearance of so-called acidosis products in the urine, and consequently to a relative increase in the urinary ammonia. *A tendency to acidosis* therefore exists. The acidosis may reach a considerable degree of severity and cause the tension of carbon dioxide in the alveolar air to become diminished.

Another interesting metabolic change in fever concerns *the salt balance.* This is studied by observing the amount of sodium chloride excreted by the urine. As is well known, this becomes markedly diminished until the crisis of the fever, when it suddenly increases. The salt retention is related to the concentration of the blood, a marked rise in which is usually accompanied by a rise in temperature and is an unfavorable prognostic sign. Salt retention is more marked in certain types of fever than in others, and it is essentially different in nature from the salt retention that has been observed to occur in nephritis. This difference has been brought to light by examination of the chloride content of the blood. In nephritis, the concentration of chlorides in the blood is considerably increased, whereas in fever it is markedly diminished. The deficiency in salt elimination cannot be attributed to a deficiency of salt in the food, for it sets in before the diet has been curtailed and, when salt is given to a febrile patient, it is retained in the body to a greater degree than is the case in the normal individual.

Belonging to this group of fevers must also be considered the important ones produced by the intravenous injection of certain forms of protein, as those of egg white or those derived from the bodies of bacteria or from the laked corpuscles of a foreign blood. The fever in these cases is without doubt caused by a mechanism closely related to that responsible for anaphylaxis. It is believed that many cases of so-called aseptic fever, occurring after severe contusions or other wounds, may be the result of destruction of proteins within the body. Similarly the rise in temperature during infections may be attributable to the breakdown of protein by microorganisms within the cells.

Nervous Factors in the Production of Fever.—Since fever is essentially the result of an exaggeration of the processes which the body normally uses to prevent a fall in temperature, we may expect to find in action those nervous mechanisms which bring about decreased heat loss and increased heat production.

Pinkston[628] has reported that the febrile reaction in rabbits which results from the injection of typhoid-paratyphoid vaccine causes a marked constriction of the blood vessels of the normally innervated ear. The response normally begins very soon after the injection, and persists until the peak of the temperature rise has developed. He found that when the sympathetic supply to one ear was cut, constriction occurred there in only one-half of the cases. In some of these it occurred immediately after injection of vaccine; in others the response came on only after a delay of one to three hours. The former type

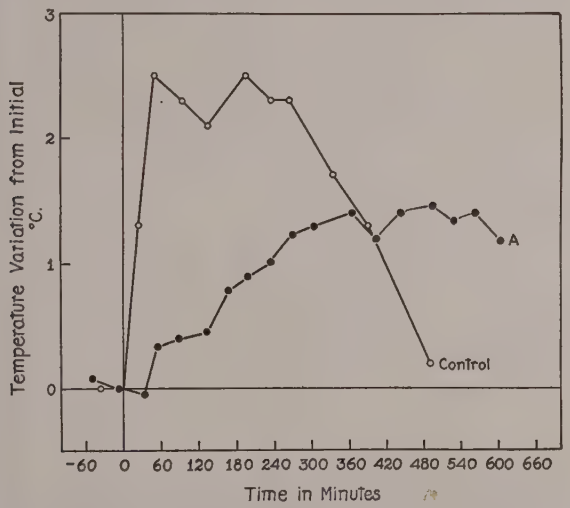

Fig. 320.—Representative fever curves from a normal cat (Control) and from a cat (A) in which both sympathetic chains had been removed from the stellate ganglia to the fifth lumbar ganglia, inclusive. Typhoid-paratyphoid vaccine injected intravenously at 0 time. (From Pinkston: Am. J. Physiol. 111: 539, 1935.)

of reaction was abolished by inactivation of the adrenals, which indicates that fever may cause a liberation of adrenalin. The delayed response shown by some of the animals was not affected by adrenal inactivation and is of unknown origin. In a second study Pinkston[629] obtained evidence that sympathetic activity in general accounts for a considerable fraction of the fever evoked by injection of vaccine. In this work cats were used. After complete interruption of all sympathetic impulses to effectors had been carried out by removal of both lateral chains of ganglia, there was a pronounced delay in the onset of the febrile reaction and in the attainment of the maximal increase (Fig. 320). When only the splanchnic outflow was left intact, the sympathetic supply to the periphery being destroyed, the fever curves were similar to those yielded by completely sympathectomized animals. On the other hand, the

curves obtained with cats with only the splanchnic nerves sectioned or with adrenals inactivated were only slightly different from those of normal cats. Previously Cannon and Periera (1924) had obtained evidence that secretion of adrenalin occurs in fever. If this is so, some of the rise in temperature may be due to its calorigenic action. Pinkston's results do not exclude this possibility, but they especially emphasize the part played by sympathetic vasoconstrictor impulses to the skin. It is obvious that when the latter are excluded, heat loss from the skin delays the onset of fever, causes the temperature to rise more slowly, and prevents the attainment of the usual maximum (Fig. 320).

Significance of Fever to the Organism

It is impossible at present to state definitely whether fever is a reaction of the organism against infection and therefore of benefit in assisting the organism to combat it, or whether it is in itself an unfavorable condition. The question can certainly not be answered by observing the behavior of bacteria growing at different temperatures in various media outside the body. That certain bacteria should be found not to thrive at incubator temperatures equal to those found in the body during fever, does not at all prove that this fever is of significance as a means of combating the growth of the bacteria in the body. It is undoubted that, where the body temperature becomes excessively high, the correct treatment is to keep it down as much as possible. On the other hand, the reduced mortality that has followed the introduction of the cold-bath treatment in typhoid fever may not be due so much to the reduction in body temperature itself as to the favorable effect produced on the nervous system and circulation. We certainly know that in normal animals moderate degrees of hyperpyrexia brought about by exposure to moist heat are well borne for considerable periods of time, thus indicating that it is the infection and not the hyperthermia that causes the serious damage to the body in infectious fevers.

PART VI

THE PHYSIOLOGY OF THE ALIMENTARY TRACT

By George R. Cowgill

CHAPTER LX

FUNDAMENTAL PHENOMENA OF GLANDULAR ACTIVITY

For the body to maintain itself it is necessary to ingest food. Materials which can serve as food must be capable of passing into the substance of the body itself. Some food materials are readily absorbed whereas others require certain chemical changes in their molecules before they can be utilized. The process by which these substances are thus prepared for actual use by the organism is called digestion. The organs which function in relation to this process are those of the alimentary tract. It is not our purpose here to discuss the detailed chemistry of food materials. This will be found in the section on Metabolism and Nutrition. It is pertinent to our present theme, however, to point out that chemical analysis alone does not necessarily suffice to determine whether a given substance can serve as a food. For example, the organic chemist regards starch as a polysaccharide which yields glucose on hydrolysis. To the student of alimentation, however, a starch, to be a food, must be capable of undergoing this hydrolysis to yield glucose *within the alimentary tract*. In other words, there is an inherent, purely biological factor which must be considered before one can say that a given complex substance is truly a food. The organs of the alimentary tract are the ones particularly concerned in the physiological operation of this biologic factor. It is our purpose here to discuss the functioning of these organs.

It will be convenient to consider, first of all, certain properties that are common to the digestive glands, and then the conditions under which each gland functions during digestion.

MICROSCOPIC CHANGES DURING GLANDULAR ACTIVITY

Structurally the active part of the glands, represented by the acinus or tubule, is composed of a basement membrane lined internally with the secreting epithelium. Outside the basal membrane are the lymph spaces and blood capillaries. The process of secretion involves fundamentally the passage of certain raw materials from the blood and lymph through the capillary wall into the lymph spaces and then through the membrane of the epithelial cell into the cell interior; there certain chemical and physical changes occur resulting in the elaboration of substances characteristic of the secretion of that cell and the discharge of them along with other materials not peculiar to the secretion alone, such as water and electrolytes, for example. As in many other physiological processes, there are

obviously two phases of the secretion process to be considered, one which covers the changes occurring when the cell is resting, or preparing for a later period of activity, and the other dealing with the phenomena of active elaboration and discharge of the secretion.

After the gland has been at rest, the cells become filled with granules or small globules, which are often so numerous as almost entirely to obliterate the nucleus. When the gland becomes active, on the other hand, the granules or globules leave the cells, except for a few which remain toward the lumen border

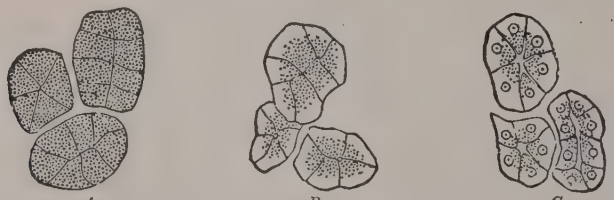

Fig. 321.—Cells of parotid gland showing zymogen granules: *A*, after prolonged rest; *B*, after a moderate secretion; *C*, after prolonged secretion. Note that prolonged secretory activity is associated with marked decrease in the number of zymogen granules. (From Langley.)

Fig. 322.—Parotid gland of rabbit in varying states of activity examined in fresh state. The upper left-hand acini are resting. The upper right-hand acini are from a gland stimulated to activity by injecting pilocarpine, and the two lower acini from one after stimulation of its sympathetic nerve. (After Langley.)

(Figs. 321 and 322). These observations indicate that the granular or globular material must represent part at least of the secretion of the glands. Sometimes, before they are extruded, the granules become changed in some way, as is indicated by the fact that they stain differently from those of the resting gland. It must not be thought, however, that an extrusion of granules *necessarily* accompanies secretory activity, for under certain conditions a copious secretion of water and inorganic salts, as well as a certain amount of organic material, may be produced without any change in the arrangement of the granules. In such

cases it has been observed, as in the pancreas, that fine channels develop in the protoplasm of the cell (Fig. 323).

From this histological evidence it would appear that the gland cell during rest is endowed with the property of building up out of the protoplasm, as granules or globules, the material which is to serve as one of the main organic constituents of the secretion. It is commonly believed that this is the precursor of the active ferment of the secretion; hence, its name, *zymogen* (leaven + producer). It has been shown that the process of separation of the zymogen granules starts around the nucleus with the production of a basophile substance, which in hardened specimens sometimes takes the form of filaments. From this basophilic *ergastoplasm* (to work + plasm), as it is called, the granules are gradually formed, and for some time continue to undergo slight further changes, as is

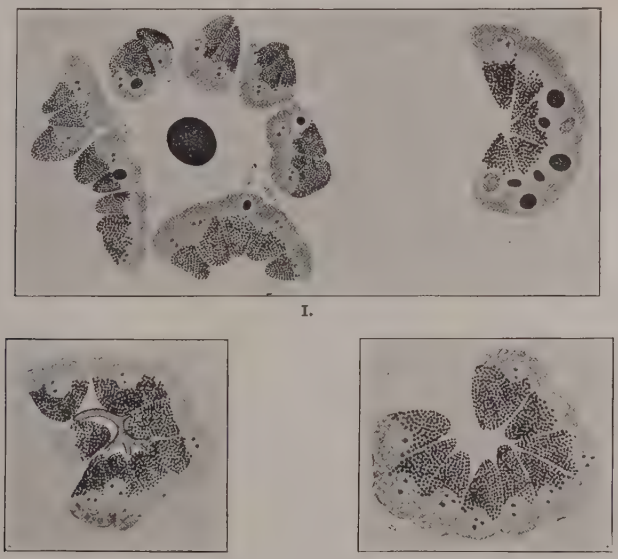

Fig. 323.—Three preparations of pancreatic acini stained by eosin orange toluidin blue. The acini of I were from a gland after vagus stimulation, and it is noted that besides free extrusion of the granules, globules staining with orange (and appearing in deep black in the photograph) have formed and may be present in the ductules. Some of the globules, however, change in their staining properties, becoming light red (dark gray in photograph). The acini in II and III were from glands excited by secretin. No globules appear; the granules remain, and fine canaliculi appear in the clear protoplasm. (From Babkin, Rubaschkin and Ssawitsch.[10])

evidenced by the fact that the staining reaction of those near the base of the cells differs from that of those at the free margin. When the gland cell is excited to secrete, the granules before being extruded, as noted above, often undergo a definite change, becoming swollen and more globular in shape.

MECHANISM OF SECRETION

These microscopic studies merely tell us that active changes, associated with the production and liberation of certain of the constituents of its secretion, are occurring in the gland cell, but they throw no light on the mechanism whereby

the gland cells secrete *water and inorganic salts*. This may be dependent, to a certain extent at least, on differences in osmotic pressure. A possible explanation of the flow of water is as follows: If a watery solution of some osmotically active substance is put in a tube, which is closed at one end by a membrane impermeable to this substance and at the other by one permeable to it, and the tube immersed in water, a continuous current will be found to issue from the permeable end so long as there remains any osmotically active substance in the tube. If we assume, then, that the membranes at the two ends of the secreting cell are of such a nature that the one next the basement membrane is impermeable to some osmotically active substance manufactured by the cell, and the other toward the lumen is permeable, it will be clear that, so long as this substance exists in the cell, it will attract water from the blood, and the water together with the osmotically active substance will be discharged into the lumen.

The foregoing explanation based on the operation of the known laws of osmosis obviously is not complete, for we know that the gland cell has the power to change quickly from a resting to an active state. Evidently there is some mechanism by which the permeability of the membrane at the lumen border of the cell can be changed readily. One school of workers believes that this is a characteristic response of the cell to any stimulus, and endeavors to relate this change to alterations in surface tension brought about by the migration of electrolytes to the border. As evidence for this view, A. B. Macallum cited his demonstration of the migration of potassium to the membrane through which the most active transfer must be taking place. In the cells of the salivary glands, this would be the lumen border; in the epithelium of the small intestine, it would be the end next to the basement membrane.

Another point of view emphasizes the effect of an intracellular splitting of large molecules to yield smaller ones with a resultant increase in osmotic pressure and attraction of water from the blood and lymph into the cell. It has been observed in those cells which contain *zymogen granules*, that the granules near the lumen border become swollen by absorbing water, and become converted into spheres in which salts are dissolved in smaller proportions than exist in the lymph bathing the cells. These swollen structures are then ruptured at the periphery of the cell and discharged into the lumen. This discharge of a fluid containing fewer saline constituents than the cell or surrounding blood plasma brings about increased concentration in the remaining parts of the cell, a process which possibly is assisted by a breaking up of molecules in the protoplasm itself, and which causes an increase in osmotic pressure with a consequent flow of water from the lymph to the cells and therefore from the blood to the lymph. This view is supported by the recent studies by Langstroth and associates[71, 72] of the secretion of protein material by the submaxillary gland following stimulation of the parasympathetic nerve supply. These investigators interpreted their data as indicating that "(a) the mechanism responsible for the secretion of protein material, that responsible for the secretion of water, and that controlling membrane permeability, operate at rates dependent on the rate at which some activating substance is liberated within the gland by the stimulation, and (b) the mechanism responsible for the secretion of protein material consists of a chemical reaction which transforms granule material to a form readily carried out of the cells by the flow of water."

It must be evident that, whatever may be the detailed explanation of the secretory process, it involves work, an expenditure of energy by the secreting cells. Experiments have revealed that during active secretion the pressure within the duct may become even greater than that in the arteries, a condition which could not result if simple filtration were the fundamental and only process. If the cells are able to secrete against a significant pressure, they do work in the process.

CHANGES DURING GLANDULAR ACTIVITY

As in other physiological processes, the secretory activity of cells is associated with a considerable expenditure of energy. The energy changes associated with the resting state are relatively small but nevertheless definite, in contrast to the markedly greater expenditure characteristic of secretory activity. Perhaps the simplest way to study this is to observe the oxygen consumption of the gland. Such observations made on the submaxillary gland of the cat reveal that the change from rest to activity may be associated with as much as a fivefold increase in the consumption of oxygen; furthermore, this increased use of oxygen continues for some time after secretion has stopped, which doubtless means that the energy thus represented is used to build up a new supply of zymogen granules as part of a recovery process. The work of Northup[99] suggests that the creatine phosphate-glycogen mechanism, which operates for the release of energy in muscle contraction, also plays a role in the energy metabolism of the salivary glands.

Secretory activity is also associated with definite changes in electric potential when the active gland is compared with surrounding nonglandular tissue. In this respect, therefore, glands resemble other organs of the body. The studies of Lim, Ivy, and McCarthy[74] on the activity of the gastric glands have shown that one phenomenon common to all secretory activity of the stomach, however induced, is an increased flow of blood through the glands, from which one might be led to suspect that the electric differences are due to these vascular changes. Experiment, however, clearly indicates that this cannot be true, for the electric phenomena occur even when the blood supply is cut off from the gland and as long as the gland continues to secrete under these conditions. Furthermore, it is possible to bring about the vascular changes without concomitant secretion, and under these conditions, the electric changes are not observed; neither is the electric change due to movement of fluid along the duct, because it may be obtained after the duct has been ligated.[20]

The increased vascularity of glands associated with secretory activity would lead one to expect an increase in volume such as occurs, for example, in the kidney. On the contrary, however, it has been shown that the immediate change following a sudden increase of activity, such as can be induced by stimulating the nerve supply, is a decrease in volume. This might be explained as due to the volume of the material stored in the gland cells and then lost in the secretion being greater than the volume representative of the increase in blood and lymph, the net change in volume of the gland therefore being a decrease.

There are drugs which exert opposite effects on glands: atropine paralyzes the secretory process, whereas pilocarpine and acetylcholine promote the flow of secretion. These agents act in such a way as to mimic or block the effects of

nerve impulses in postganglionic parasympathetic secretory nerves and therefore may be used in experiments to determine certain details of the nerve supply to the gland; nicotine blocks conduction across the synapses in autonomic ganglia, and may therefore be used along with the above-named drugs to determine whether certain ganglia are parts of the nervous mechanism involved in the activity of the gland. The ability of atropine to inhibit secretory activity is made use of by the clinician in treating rhinitis and other conditions which are characterized by profuse flow of secretions.

Important observations concerning *the relationship of glandular activity to the blood supply* have been made by experiments in which glands were artificially perfused outside the body. When the submaxillary gland of the dog is perfused with oxygenated Ringer's solution, stimulation of its nerve supply does not produce the usual secretion, but if the Ringer's solution is mixed with blood plasma, the nerve stimulation has its usual effect for a short time. Although no secretion occurs when the oxygenated Ringer's solution is perfused alone, the usual vascular changes still occur in the gland. The results seem to indicate that the presence of some constituent of the blood plasma is essential for the change in the permeability of the cell wall necessary for the process of secretion. Similar results have been obtained during artificial perfusion of the pancreas when secretin was used as the stimulus.

CONTROL OF GLANDULAR ACTIVITY

Having outlined the general nature of the changes occurring in gland cells during their activity, we may now consider the nature of the process by which this glandular activity is controlled. Two mechanisms of control are known: (1) by the nervous system, and (2) by means of chemical agents, the hormones.

Nervous Control

Control through the nervous system is most highly developed—indeed, it may be the only means of control—in glands which are required to produce their secretion promptly, whereas hormone control predominates in those in which prompt changes in secretory activity are not demanded. Thus, nervous control alone is present in the salivary glands, whereas hormone control is predominant in the pancreas, intestinal glands, and in the liver. The gastric glands are partly under nervous control, and partly under hormone control. There are other glands, nondigestive in nature, which are also subject to either nervous or hormone control, according to the promptness with which they are required to secrete. The lacrimal and sweat glands, and the venom glands of reptiles, for example, are practically entirely under nervous control, whereas most of the ductless glands are mainly under the influence of hormones. The exact nature of the nervous control of glandular function has, therefore, been most extensively studied in the salivary glands, and that of the hormonal in the pancreas.

The nerve supply of the salivary glands comes from two sources, the bulbar autonomic (parasympathetic) and the thoracolumbar autonomic (sympathetic). These two innervations do not have the same influence on the secretory activity of the glands and in general they exert opposite effects on the blood vessels

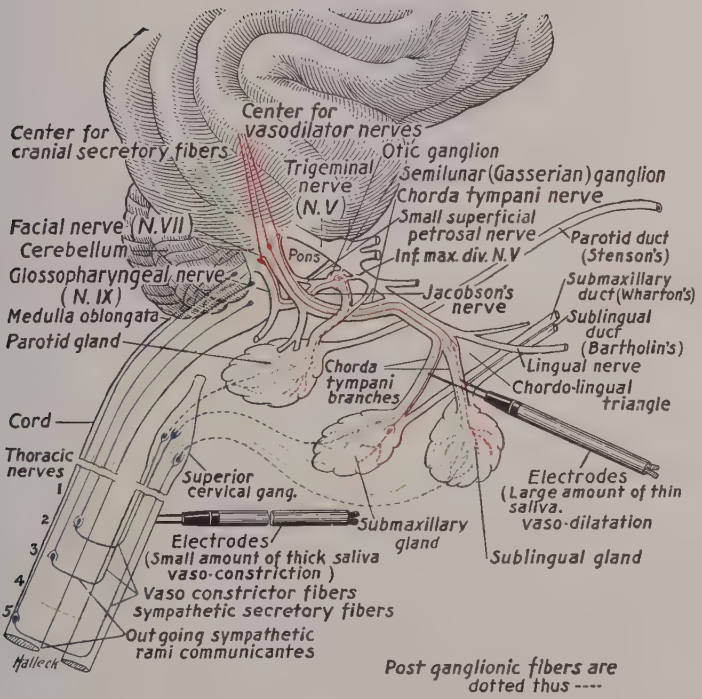

Fig. 324.—Diagrammatic representation of the innervation of the salivary glands in the dog. (After Jackson.)

of the glands; the parasympathetic is vasodilator, the sympathetic vasoconstrictor. In all species of experimental animals a fairly copious flow of secretion can be obtained from any one of the salivary glands by stimulation of its parasympathetic supply. A similar response results from administration of the drug pilocarpine. In the case of the secretory activity of these glands we do not have an example of the rather general rule that when fibers of the two divisions of the autonomic system meet in an effector tissue they exert opposite effects, i.e., excitatory and inhibitory. Stimulation of the sympathetic supply also produces salivary secretion but, "Neither from the submaxillary, the sublingual, nor the parotid gland of any animal does the sympathetic produce a secretion which approaches in amount that which is produced by the cranial nerve." (Langley.) For example, in the dog, faradic stimulation of the sympathetic for a minute produces only two or three drops from the submaxillary gland and even less from the parotid. There are slight species differences; relatively, a little more sympathetic secretion is obtained in the cat and rabbit than in the dog.

On account of their ready accessibility, the submaxillary glands of the dog and cat have been most thoroughly investigated. Here the parasympathetic supply (preganglionic) is represented by fibers of the facial nerve which course in the chorda tympani, and the sympathetic by fibers (postganglionic) that run from the superior cervical ganglion to the gland along its blood vessels (Fig. 324). The parasympathetic postganglionic fibers arise in ganglia which lie mainly in the hilus of the gland, but in part along the distal portions of the chorda tympani. After tying a cannula in Wharton's duct it can be shown that stimulation of the chorda produces an immediate and abundant secretion of rather watery saliva which is accompanied by a marked dilatation of the blood vessels of the gland. It can easily be shown that this secretion is not dependent on the vasodilatation by repeating the experiment after administering a dose of atropine. Stimulation of the nerve then produces vasodilatation but no secretion. Some authorities consider that the atropine acts on the secreting cells in some way, interfering with the secretory process itself; others interpret such observations as due to action of the drug on the endings of the secretory nerves preventing the transfer of excitation to the gland cells, or the chemical changes by which such transfer may be effected. Whatever may be the details of this mechanism, it is clear that one may describe the action of atropine as paralyzing the glands.

The vasodilatation phenomena suggest that the secretion of the gland might be the result of a filtration process; and for this hypothesis to be true, one should always find the secretory pressure within the duct less than the pressure in the capillaries of the gland. Actual experiment reveals, however, that the pressure within the duct may be even greater than that in the arteries, and therefore vasodilatation cannot be responsible for it. This pressure difference is indicative of work done and energy expended by the gland cells in manufacturing and discharging their secretion. For this much oxygen and doubtless other materials are needed, and they are provided in greater abundance by the increase in blood flow. In contrast to these effects, stimulation of the sympathetic nerve supply results in a scanty discharge of a thick viscid secretion concomitant with vasoconstriction.

The production of two such distinct types of secretion, one thin and watery, containing only a small percentage of organic matter, and the other, a thick viscid secretion with a large amount of organic material, has been explained by the hypothesis that there are two kinds of secretory fibers, which Heidenhain called secretory and trophic, the former having to do with the secretion of water and inorganic salts, and the latter with the secretion of organic matter; i.e., with the extrusion of the zymogen granules. This view is supported by the more recent study of Sergeyeva[111] who investigated the effect of various stimuli on the presence and location of zymogen granules in the cells of the pancreas; the results were interpreted as affording "an exceptionally good illustration of the type of nerve effect which Heidenhain designated 'trophic.'" Thus, in the cat the vagus supply to the pancreatic acinous tissue is considered to be purely "trophic" in nature in contrast to the humoral stimulus which elicits a "secretory" effect. Other authorities have suggested that the differences in the secretions resulting from parasympathetic and sympathetic stimulation are due to the different effects of these nerves on the blood vessels of the glands. Although it may not be doubted that vascular changes may influence the quality as well as the quantity of salivary secretion, this explanation can scarcely account for the fact that the dog's submaxillary gland may secrete approximately equal volumes of saliva of quite different content when reflexly excited by the presence in the mouth of two different substances. For example, meat powder provokes a secretion containing about five times as much organic solids as that which is produced by weak acid. It has been found not only that the blood flow through the gland is the same during response to these two substances, but also that the same differences in secretion persist after interruption of the sympathetic supply to the gland (Babkin). In the absence of further evidence it may tentatively be supposed that the chorda tympani contains at least two types of secretory fibers which may be selectively caused to discharge by different reflex stimuli. This would appear to be the case even if it happens that the differences in secretion depend on activation of different sets of gland cells. In considering this problem the reader should bear in mind the all-or-none nature of nerve conduction.

Studies on the salivary glands have yielded evidence in support of the view that impulses in postganglionic autonomic neurons act on the effector cells which they innervate through the agency of *chemical mediators* (see Chapter XI). According to this view, the production of saliva by stimulation of the parasympathetic fibers of the chorda tympani is associated with the peripheral appearance of a substance having the pharmacological properties of acetylcholine; sympathetic stimulation results in production of a substance resembling adrenalin (sympathin). These compounds are presumably produced in the gland and may escape into the blood stream. Dale introduced the words "cholinergic" and "adrenergic" to describe nerve fibers or impulses by reference to the chemical compound involved in the mediation of their effects. The observations of Babkin and associates,[9] constituting an application of this concept to the salivary glands, have been confirmed by several other investigators.[23] The findings of Langstroth and collaborators[72] (see page 890) readily harmonize with this view. The claim of Secker,[110] that these particular humoral agents are even present in the saliva has been challenged by Feldberg and Guimarais,[39] Gibbs,[45] and Larson.[73]

Discussion of the nervous control of secretion would not be complete without some reference to the phenomenon of *paralytic secretion*. It was discovered by Claude Bernard that if the chorda tympani nerve of a dog is cut, there occurs, after about three days, a slow continuous flow of secretion from the gland whose preganglionic parasympathetic innervation had been interrupted. After several weeks the volume of this secretion diminishes until finally the gland has atrophied and no secretion is possible. The continuous flow of saliva occurring under these conditions is called paralytic secretion and may be of some significance in clinical medicine, although its precise cause remains uncertain. When such a phenomenon is observed clinically, some disturbance in the relations of the secretory nerves to the glands in question is suggested, and this should be of interest to neurologists. In dogs exhibiting the disease black tongue, a profuse and apparently uncontrolled flow of saliva is one of the important signs that the animal is in a critical state. Such observations, considered along with the results of experiments in normal animals, support the view already set forth, that the salivary glands must be subject normally to a fairly well-balanced control exercised by the secretory nerves described above, and serious disturbances of this control are only to be encountered in disease.

Hormone Control

This is exhibited best in the case of the pancreas. The crucial experiment demonstrating that this gland is not primarily dependent upon nervous impulses for control of its activity was performed by Bayliss and Starling.[13] Starting with the well-known fact that the application of weak acid to the duodenal mucous membrane excites secretion of pancreatic juice, these workers carefully severed all the nerve connections of a portion of the duodenum, and found on again applying acid to the mucous membrane that the secretion persisted. To explain this result they postulated that the acid must cause some substance to be liberated into the blood stream, which carries it to the pancreas, the cells of which it then excites to activity. To test this hypothesis they scraped off the mucous membrane of the duodenum and ground it in a mortar with weak hydrochloric acid (0.6 per cent). After boiling the mixture so as to coagulate the protein, nearly neutralizing and then filtering, they obtained an extract which immediately caused a copious secretion of pancreatic juice when injected intravenously.

Accompanying the secretion, however, a marked fall in arterial blood pressure was observed, making it possible that the secretion might have been due to a vasodilatation occurring in the pancreatic blood vessels. To eliminate this possibility they prepared an extract that was comparatively free of the depressor substances by extracting intestinal epithelium without any of the submucous tissue. The resulting extract had merely the secretory effect and produced little or no fall in blood pressure. The active substance they named *secretin*. Inasmuch as the extracts prepared with water or salt solution contained the depressor substances but had no effect on the pancreas, they suggested that there is an inactive precursor substance, prosecretin, in the intestinal mucosa, which is activated by acids.

For many years the specific nature of secretin was challenged, particularly by Popielski, who attributed the secretory effect of tissue extracts to vasodilatin present in them. The original thesis of Bayliss and Starling received further support, however, by the discovery that vasodilatins are more soluble in alcohol than secretin; by utilizing this fact, it is possible to secure preparations which have a powerful secretory action on the pancreas when injected intravenously, but no effect on blood pressure. Mellanby[89] in 1926 succeeded in devising a method for making a very potent preparation by extracting the duodenal mucosa with absolute alcohol and then precipitating the secretin with acid, dissolving the precipitate in alcohol and reprecipitating by means of acetone. Luckhardt, Barlow and Weaver[78] made a great advance when they discovered that simple acid extraction of the intestinal mucosa—made by filling the first five feet of the intestine with the acid and allowing this to extract for thirty minutes, then neutralizing and filtering—yielded a preparation potent as a secretin but devoid of depressor substance. The necessity of attempting separation of the two factors was thus avoided at the outset. Other secretin preparations have been made by Still[112] and by Ivy and associates.[63] Secretin was finally obtained in crystalline form by Agren,[1] who made an extensive study of its physiological and chemical properties.

The secretin theory as put forth by Bayliss and Starling postulated secretin as a chemical agent elaborated in the cells of the intestinal mucosa by contact

of those cells with acids, and passing by way of the blood stream to the pancreas where it exerted its stimulating action. The isolation of secretin in crystalline form constitutes powerful support for the theory, but a critic would be justified in claiming that this means merely the isolation of a particular pharmacologic agent which can act upon the pancreas; that proof of the hormone mechanism must involve physiologic experimentation in animals. Such proof has been obtained. For example, cross-circulation experiments have been performed in which the circulations of two animals are joined and acid placed in the intestine of one of the animals, with the result that the pancreas in each animal responds by secreting juice. The work of Ivy and associates[37] has finally given us the best kind of proof desired. In their first experiments the tail of the pancreas of the dog was transplanted under the skin, thus bringing the duct to the surface to yield a fistula. Later, after new blood vessels had developed for the transplant, the original blood and nerve supply was severed. It was found that food or hydrochloric acid given by mouth provoked a characteristic secretion. These experiments were open to the criticism that food products absorbed from the intestine might have been responsible. Therefore, in later studies,[61] both jejunal and pancreatic transplants were prepared in the same dog. When hydrochloric acid was placed in the transplanted jejunum, juice was secreted by the transplanted pancreas. Suitable control materials placed in the jejunum were without effect.

The suggestion of the existence of prosecretin, a precursor of the active hormone, has not been so successfully substantiated. As Still points out in his review of literature on this problem, "the views of most workers . . . rested upon suggestive rather than conclusive data."

According to Agren[1] who used a crystalline preparation of secretin for his studies, the hormone contains about 0.68 per cent sulfur, which corresponds well to the theoretical 0.64 per cent, if the molecule contains 1 atom of sulfur and has a molecular weight of about 5,000. It contains much arginine (6.60 per cent) and histidine (3.96 per cent), some lysine, but apparently no cystine, tyrosine, or tryptophane. It behaves as a basic substance, gives some but not all of the tests for protein, and is digested by proteinases, all of which suggests that it is fundamentally protein in nature. It may be inactivated by treatment with 0.1 N sodium hydroxide, and this loss of activity is associated with the appearance of the ninhydrin reaction, suggesting that the inactivation is due to a splitting of a peptide linkage without further disruption of the molecule. The activity cannot be related to the presence of free amino groups. With respect to physiological properties, Agren's preparation was found on intravenous injection to produce secretion of the pancreas, liver and intestinal glands, an action which may be described as a "generalized intestinal diuretic" effect. It had no influence on the internal secretion of the pancreas, or on the concentration of either blood sugar or blood amylase, three effects which had been cited by earlier workers as due to secretin; in the earlier work these changes were due to other substances present in the crude extracts which were used. Pure secretin-HCl, unlike impure preparation, produces no lowering of blood pressure, no effect on the gallbladder or on isolated segments of intestinal muscle of the rabbit.

Any acid when applied to the intestinal mucous membrane is capable of liberating secretin, and so are certain other substances, such as mustard oil.

Secretin is not effective if placed in the intestinal lumen. This may be related to the ease with which it is destroyed by such digestive enzymes as those present in the pancreatic, gastric, and intestinal juices.

The pancreatic juice produced by the injection of secretin, like that elaborated under normal conditions, does not contain any active trypsin, but instead contains its precursor, trypsinogen. This becomes converted into trypsin in the intestine, being activated by mixing with enterokinase, an enzyme present in the intestinal juice. It has been suggested that this mechanism protects the mucosa of the pancreatic duct against autodigestion by trypsin but this explanation is not entirely satisfactory.

There is a nervous control of pancreatic secretion as well as that mediated through secretin. Prior to the discovery of secretin, Pavlov and his pupils had published numerous experiments to show that the secretion of pancreatic juice may be evoked by stimulation of the vagus nerve. The amount of secretion produced by nervous stimulation was, however, never as large as that subsequently found to be produced by secretin, and for several years after the discovery of this hormone, doubt existed as to the correctness of Pavlov's claim. As in many other fields of physiological science, investigators attempted to show that one or the other mechanism operated exclusively, and they were not inclined to consider the possibility that both might exist side by side. This period might also be considered as representing essentially an experimental study of the extent and limitations of the newly discovered hormone mechanism. There is little doubt, however, that the vagus nerve carries secretory fibers to the pancreas, and stimulation of them results in a flow of pancreatic juice which, besides being less copious than that following secretin injection, differs from it in the important fact that it contains not trypsinogen but active trypsin. Since normal pancreatic juice contains chiefly trypsinogen, and only a small amount of trypsin, it may be argued that the vagus control of the normal secretion cannot be as important as that mediated by the hormone secretin. The vagus secretion of pancreatic juice is, moreover, paralyzed by atropine, which has no action on the secretin mechanism.

The copious secretion of pancreatic juice produced by secretin, on the one hand, and the scanty, thick secretion evoked by vagus stimulation, on the other, call to mind similar differences observed in the secretion of saliva as the result of chorda-tympani or sympathetic stimulation. It will be recalled that from these results the conclusion was reached that there must be secretory and trophic fibers concerned in the control of the activities of gland cells. Interesting corroboration of this conclusion has been obtained by *histological examination of the pancreas following secretin or vagus activity.* After the repeated injection of secretin, it is difficult to observe any signs of fatigue in the cells; the zymogen granules remain practically as numerous as in a resting gland, but in the clear protoplasm of the outer third of the cell, it is said that fine channels can be seen. Through these channels water is believed to pass from the blood toward the lumen and in its course to carry with it some of the zymogen granules without, however, changing them. Thus, when the gland cells are stained with eosin and orange, after secretin activity some of the zymogen granules can occasionally be seen in the lumen of the acini stained with eosin like those in the cell itself.

After vagus stimulation the appearances are different; not only are the granules more decidedly removed from the cells, but they undergo a preliminary change; they lose the property of staining with eosin and become stained with orange, at the same time increasing in size so as to form vacuoles. These vacuoles may wander into the ductules, and when they are present here they are stained by orange (Figs. 323 and 325) (Babkin et al.[10]).

Why there should be both a nervous and a hormone control of the pancreatic secretion is not clear. The ideas of Langstroth and his associates[71, 72] representing essentially a combination of the Heidenhain concept of "trophic" and "secretory" stimuli and the Dale idea of "cholinergic" and "adrenergic" mediation of nervous impulses through specific chemical compounds, constitute an interesting recent approach to an answer to this question which takes account of the secretion of both water and electrolytes as well as organic complexes. In the case of the pancreas the nervous influences through both the vagus[111] and the splanchnics[8] appear to be quite definitely related to the discharge of large molecules of organic material and movement of granules, and similar to Heidenhain's "trophic" influence. Also, the hormone secretin produces primarily, although not exclusively,[68] a flow of water and electrolytes, which is a phenomenon comparable to what Heidenhain called a "secretory" response. However, the fact that secretin does to some extent stimulate enzyme production[68] makes it clear that the above statements constitute an oversimplification of the problem and do not afford a complete explanation.

The flow of pancreatic juice is important when there is food material in the small intestine, and this material would normally appear as part of a discharge of stomach contents. One can then understand the value of the secretin mechanism operating in response to the presence of the acid gastric discharge; such an arrangement would insure the proper sequence of pancreatic juice flow after gastric digestion has taken place. The pancreatic juice secreted in response to secretin contains much water and inorganic salts, chiefly bicarbonates, whereas stimulation of the vagus excites the secretion of enzymes as part of a more viscous juice. Mellanby[89] has suggested that the prime function of the juice evoked by the secretin mechanism may not be to provide enzymes but rather alkali with which to neutralize the acid discharged through the pylorus. This idea receives considerable support when one considers the results of studies of experimental duodenal ulcer. The technique found most effective by Mann and others[83] in the production of these ulcers consists in operating on animals in such a way as to divert the alkaline secretions of the pancreas and liver from that part of the small intestine which receives the acid discharge from the stomach; in this part of the intestine, unprotected (?) by the alkaline pancreatic juice and bile, ulcers appear with great regularity.

The rôle of the vagus mechanism may be similar to that of the sympathetic fibers to the salivary glands: nervous impulses coming over these fibers affect in some way the intracellular processes involved in the elaboration of the complicated enzyme molecules. There is another point of view that may be taken. When considering any digestive process that requires activation of a precursor substance or the maintenance of special conditions of acidity, or alkalinity, etc., quantitative examination of the different variables suggests that it may be relatively more important to secrete an abundance of material (alkali, or acid) needed

for securing the optimal conditions of enzymic activity (trypsin or pepsin) than to vary the amount of the enzyme secreted. It is an interesting fact that the salivary glands, the pancreas, and the stomach all give evidence of two types of processes involved in secretion, one having to do with the elaboration of special organic material peculiar to the secretion, the other, with the flow of water and electrolyte, perhaps a flushing action, through the cell. In the salivary glands, both of these processes seem to be subject to nervous control; in the pancreas, only one is under nervous control, the other being influenced by the hormone

Fig. 325.—Pancreatic acini and stained with hematoxylin. The acini at the top and to the left of the figure are from a resting gland, those to the right being from one that had been secreting for over three hours as a result of acid in the duodenum. The lowermost figure is from a gland, the vagus nerve supply of which had been stimulated off and on for several hours. Note that the zymogen granules are extruded only after vagus activity, not after secretin activity. (From Babkin, Rubaschkin and Ssawitsch.[19])

mechanism with alkali salts as the electrolytes of greatest value; in the stomach, the situation is more complicated, yet there is definite evidence that both nervous and humoral mechanisms play a rôle, the latter being concerned in the elaboration of a highly fluid secretion with hydrochloric acid as the important electrolyte; this possible rôle of the acid secretion of the parietal cells of the gastric mucosa in flushing the tubular glands and thus washing out their thick pepsin or

pepsinogen-rich product of chief cell activity, is illustrated in the experiments of Gilman and Cowgill,[47] which will be discussed in more detail when we come to consider gastric digestion.

As was emphasized before, when discussing the dual nervous control of salivary secretion, it is reasonable to believe that the two types of gland control, nervous and hormonal, operate together to secure a balanced control which is capable of some normal degree of variation to meet special situations; and that it is possible for one or the other of the extreme conditions, represented by failure of either control mechanism to operate in appreciable degree, to occur either as the cause or the result of disease. As an illustration of this last point, we may cite the observation of Ivy et al.,[38] that pancreatic dysfunction (failure to provide proper alkali [?]) may be associated with hypersecretion of gastric juice.

CHAPTER LXI

PHYSIOLOGY OF THE DIGESTIVE GLANDS

In the preceding chapter the fundamental phenomena characteristic of the secretory process were described. The cells endowed with the property of elaborating digestive secretions are found gathered together in many organs forming parts of the alimentary tract. No one gland serves all of the digestive needs of the body; each cooperates, as it were, with the other glands. As food passes through the alimentary tract, the different secretions are called forth in appropriate order, and each performs the specific rôle assigned to it, with the result that all foods requiring digestion have been duly subjected to this process and the products given ample opportunity for absorption by the time the swallowed food has passed through the ileocecal valve into the large intestine. The conditions under which each gland elaborates and discharges its secretion, being numerous and varied and correlated with the activities of other organs, must be studied if the student of physiology and medicine is to understand the basis of certain diseases of the alimentary tract.

THE SECRETION OF SALIVA

Methods of Study

A simple method for studying the mechanism of salivary secretion consists in isolating a salivary duct in an anesthetized animal, tying in it a cannula, and observing the flow of saliva under various conditions. It was by means of such a technique that the fundamental observations concerning the rôle of certain nerves, drugs and hormones were made. It is clear, however, that the conditions of such experiments are far from ideal, because they tell us nothing about the possible responses of the salivary glands to stimuli operating in a conscious normal organism. Pavlov succeeded in devising a permanent salivary fistula thus meeting the chief criticism of the older technique. The mucous membrane surrounding the opening of the duct is cut to form a small disk of tissue at the center of which is the duct opening. The duct is freed a short distance by careful dissection, and the disk then passed through a wound in the cheek to the outside where it is sewed to the edges of the skin wound. Healing takes place without the formation in the duct of any stricture due to scar tissue. After the wound has healed, the secretion can readily be collected in a receiver over the duct fistula, the animal being in every other way in a perfectly normal condition. By using a graduated receiver of glass, the experimenter can readily observe and measure in a wide-awake, sensitive animal, the saliva secreted in response to various experimental conditions. The fistula can be made with the duct of the submaxillary gland, in which case the secretion is from a mucous gland; if the duct from the parotid is employed, the secretion is from a serous gland. In preparing a permanent salivary fistula of the Pavlov type, the dog has been found to be especially valuable.

Factors Causing Secretion of Saliva

Inasmuch as the salivary glands are entirely under nervous control, this may be made the basis for a simple classification of the types of secretory responses. When secretion occurs, it is caused by impulses acting on a nerve center or centers in the medulla oblongata, the exact location of which for the different glands has been worked out by Miller.[93] The impulses acting on these centers

may be transmitted along afferent nerves coming from the mucous membrane of the mouth, nares, etc., or they may come from the higher centers over pathways within the brain.

Unconditioned Responses.—Secretion may be obtained by a simple reflex mechanism, through stimulation of various receptors located in the mouth. This reflex is remarkably prompt when an irritating substance is placed in the mouth, the copious secretion acting to dilute the irritant and to aid in its removal. There is some degree of adaptation of the secretion to the physical state of the material. If the dog is given meat, there is a secretion of thick viscous saliva chiefly from the submaxillary gland; if, on the other hand, the meat is dried and pulverized, the secretion which it calls forth will be very copious and watery, the product of parotid gland activity. The mucous secretion called forth by meat will serve to lubricate the bolus of food and thus facilitate its swallowing, whereas the thin watery secretion produced by the dry powder will have the effect of washing the powder from the mouth. Although mechanical stimulation of the mucosa seems to be quite effective in some instances, there are situations in which it does not seem to be adequate. For example, the presence of pebbles in the mouth calls forth but little secretion whereas with sand, secretion immediately becomes copious. Chemical stimuli are also effective. Thus, weak acid causes a copious secretion, while weak alkali has no effect; disagreeable, nauseous substances also excite secretion. The above differences in the response of the glands according to the mechanical condition of the food have been observed in the case of the parotid gland, increase in the submaxillary secretion being obtained only when foods are actually placed in the mouth. It is evident that, with at least two different types of glands able to function, a considerable range of variation is possible with respect to the properties of the mixed secretion finally discharged.

Conditioned Responses.—The investigations that have been made on the conditions of psychic secretion of saliva are still more interesting and important. Their importance depends not so much on the information they give us concerning the secretion of saliva as such, as on the methods they afford us for investigating the various conditions that affect the psychic processes associated with the taking of food. It is from the psychic rather than from the physiologic standpoint, therefore, that these observations are of importance, for they permit us, by objective methods, to study on dumb animals problems that would otherwise be beyond our powers of investigation. Many of the results, with their bearing on the functions of the higher nerve centers, have been discussed elsewhere (Chapter XX). Meanwhile, however, even at the risk of repetition, it may not be out of place to cite a few of the most interesting experiments.

If a hungry animal is teased with a food for which he has a great appetite, a copious secretion of saliva immediately occurs. If the teasing is continued without giving him the food, and the procedure repeated on several succeeding days, it will be found that he responds less and less to the teasing by salivation. Evidently, therefore, the reflex is conditioned by the animal's receiving the food. The dog may be conditioned to secrete saliva in response to the sound of a particular tuning fork by the simple procedure of always sounding the fork just before the food is given; eventually the animal responds to the sound of the fork although no food is given.

It is possible to condition the dog to secrete saliva in response to the smell and sight of a food for which the animal has no appetite. To do this, we repeatedly offer first of all the unappetizing food, followed, after a time, by presentation of the appetizing food. Eventually the animal secretes saliva when the unappetizing morsel is offered. He has learned to associate the presentation of the unappetizing food with the subsequent gratification of his appetite. The experiment can even be performed so that a definite interval of time elapses between the application of the stimulus and the salivation: if the animal is teased on successive days with food for which he has an appetite but is not given the food until after ten or twenty minutes, presentation of this food will come to be followed by salivation—not immediately, but after the exact interval of time that had been allowed to intervene in the training process. During this interval there must be an inhibition of psychic stimulation of the salivary centers by other nerve centers. It is of great interest that this inhibition may itself be inhibited by various forms of stimulation of the nervous system (see page 233).

THE SECRETION OF GASTRIC JUICE

Methods of Investigation

Unlike the salivary glands, which are provided with ducts, the stomach is essentially a bag, the entire lining of which contains glands whose secretion is eventually discharged into the intestine; this bag is also able to receive swallowed material which may be both food and saliva. The problem of securing pure gastric juice for study is therefore a much more difficult one to solve. One of the most interesting chapters in the history of physiology concerns the methods which from time to time have been evolved for the collection of this juice and for studying the digestive processes in the stomach.

The earlier investigators concerned themselves with tests of the various ideas of gastric function which had been suggested. Hippocrates, who has been called the Father of Medicine, took as his illustration of the digestion which occurs in the stomach the solution of foods which results from cooking; heat coction was considered to be the fundamental process. It was realized that the living organism is capable of producing heat, and this idea was combined with the other, resulting in the hypothesis that the stomach is the locus of heat production and gastric digestion is essentially a solution of food by heat. The Belgian philosopher, Van Helmont (1577-1644) likened digestion to the fermentation processes in nature; Sylvius (1614-1672) taught his medical students in Leiden that gastric digestion is a fermentation. The French philosopher and mathematician Descartes (1596-1650), and the English anatomist Willis (1621-1675), used the observations of physicians that acid material is present in vomitus as the basis for the suggestion that gastric digestion is brought about through the elaboration of some powerful acid similar to nitric or phosphoric acid, the most potent acids then known. Borelli (1608-1679), the Italian engineer, who brought his talents to bear on problems of physiology, likened the stomach to the crop of the bird, and suggested that the chief function of the stomach is to grind the food. The first really experimental attack on the problem was made by the great French scientist Réaumur (1683-1757), who performed numerous experiments on a pet kite, able to regurgitate the bones of its prey. Hollow spheres and similar objects with perforated walls which could resist crushing, were filled with different kinds of foods and then given to the bird. After having been regurgitated, these were examined. It was found that meat had dissolved whereas cereal grains and certain other foods were practically unaffected. Sponges were also placed in these special containers, and when regurgitated, were squeezed dry of the gastric juice which they had absorbed. This work was followed by that of the Italian Abbé Spallanzani (1729-1799) who employed similar methods, notably the use of small

perforated wooden tubes containing foodstuffs and covered by small linen bags. After the bags were passed through the rectum, he found that considerable erosion or digestion of the food had occurred, but that the wooden tubes, however thin-walled they might be, were not crushed. In order to secure samples of the gastric juice free from food, these earlier investigators resorted to the technique of swallowing sponges attached to threads, which after being in the stomach for some time were withdrawn and squeezed dry of juice. The last sentence in Spallanzani's treatise, "the gastric juice is antiseptic," is a famous one because of the extent to which it has been confirmed in later researches.

The next great contribution came from the United States. Dr. Beaumont, a surgeon in the service of American troops located at Mackinaw in northern Michigan, reported in 1833, his observations made on a Canadian voyageur by the name of Alexis St. Martin, who by the premature discharge of his gun had wounded himself in the stomach. The wound, which never completely healed, left a permanent gastric fistula. Beaumont found it possible to see through this fistula the interior of a normal living stomach. This opportunity was capitalized by arrangements to keep Alexis St. Martin in Dr. Beaumont's service for several years, during which time numerous observations were made on the process of digestion in the stomach—observations many of which are of great value even at the present day. Many of the statements found in textbooks concerning the relative digestibility of common foods in the stomach are based upon the reports of Dr. Beaumont.

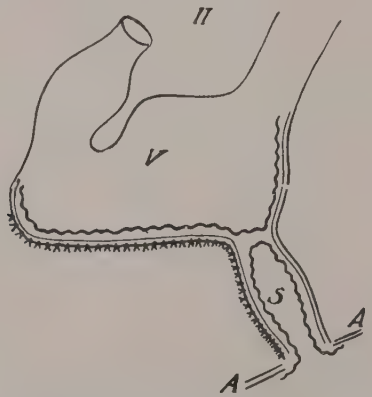

Fig. 326.—Diagram of stomach showing miniature stomach (*S*) separated from the main stomach (*V*) by a double layer of mucous membrane. *A.A.*, is the opening of the pouch on the abdominal wall. (Pavlov.)

The publication of Beaumont's observations soon stimulated physiologists to make similar fistulas in animals. It is evident, however, that even a simple fistula of the Alexis St. Martin type cannot yield pure gastric juice uncontaminated by swallowed saliva or material regurgitated from the intestine. Heidenhain attempted to solve this problem by cutting the stomach in such a way as to make two separate pouches, one retaining its connections with the esophagus and intestine, the other draining through an opening in the abdominal wall. The results of Heidenhain's experiments are, however, open to the objection that the secretion of the isolated pouch may not really correspond to that occurring in the main stomach, since the connections of the isolated pouch with the central nervous system must have been severed. His pupil, the Russian physiologist, Pavlov, devised an ingenious improvement on his operation in which the pouch or "miniature stomach" remains connected with the main stomach through a considerable width of mucous and submucous tissue and in which the nervous connections are not severed. The essential nature of this operation will be evident from the accompanying diagram (Fig. 326).

More recent observations have been made by Cannon, Carlson and Ivy. Cannon fed animals food impregnated with bismuth subnitrate, and then exposed the animal to the x-rays. A

shadow is produced by the food mass in the stomach, and from the changes in the outline of this shadow facts have been collected, not only concerning the movements of the viscus, but also concerning the rate of discharge of food into the intestine and therefore the duration of the gastric digestive process. Carlson's contribution has been rendered possible by his good fortune in having in his service a second Alexis St. Martin (called "Mr. V" in the literature), a man with complete closure of the esophagus and a gastric fistula large enough to permit of direct inspection of the interior of the stomach. Ivy has utilized the techniques of modern surgery to prepare in dogs the Pavlov or Heidenhain pouch combined with isolated loops of the intestine or other operations of value in elucidating the fundamental mechanisms involved in gastric secretion.

The Cephalic Phase of Gastric Digestion

The first stimulus to the secretion of gastric juice is nervous in origin, involves the brain, and is dependent on the stimulation of various receptors located in the head. The earlier investigators attributed this to the gratification of the appetite and the pleasure of taking food. Following suggestions made by certain observations in the clinic, Pavlov was the first thoroughly to investigate this problem. For this work he used dogs provided with the "miniature stomach" and an esophageal fistula. When food was given by mouth to these animals, it was chewed and swallowed in the usual manner, but before reaching the stomach, it escaped through the esophageal fistula. This experiment is known as "sham feeding." Within a few minutes after giving food the gastric juice was found to be secreted actively and if the feeding process was continued, which could be done almost indefinitely since the animal never became satisfied, the secretion continued to flow. Thus, in one instance Pavlov succeeded in collecting about 700 ml. of gastric juice after sham feeding an animal for five or six hours in the manner above described. The presence of food in the mouth is undoubtedly the most effective stimulus of this flow of so-called psychic juice. The stomach of Carlson's patient would not secrete in response to the mere thought of food, but was stimulated when food was actually present in the mouth. Pavlov considered that the secretion obtained under these conditions was definitely associated with activity of the higher centers in the brain, and therefore should be called a "psychic secretion."

The sham feeding causes stimulation of the gastric secretion through impulses transmitted to the stomach along the vagus nerves; for it has been found, in animals in which the vagus nerve has been cut, that the sham feeding no longer induces a secretion of gastric juice. The question therefore arises as to how the nerve center is stimulated. Three possible causes may be considered: (1) mechanical stimulation of the sensory nerves of the mouth; (2) chemical stimulation of these nerves; (3) the agreeable stimulation of the taste buds and olfactory endings concerned in the tasting of food. In investigating these possibilities, mechanical stimulation was readily ruled out by showing that mere taking of solid matter in the mouth did not excite any secretion, although it might cause a flow of saliva. Mere chemical stimulation could not be the cause, for no secretion was induced by placing substances such as acetic acid or mustard oil in the mouth. By exclusion, then, it would appear that the adequate stimulus must consist in the agreeable stimulation of the taste buds, etc. This would constitute support for Pavlov's idea that there is a psychic factor involved.

Further justification for this conclusion was readily secured by noting that foodstuffs for which the animal had no particular desire or appetite failed to excite the secretion. Most dogs, for example, although they may take it, are not particularly fond of bread, and when fed with it, these animals do not produce any appetite juice. In one animal that showed considerable liking for bread, active secretion occurred when he was fed with this foodstuff.

Pavlov further noted that usually it was not necessary actually to allow the animal to take the food into his mouth, but that mere teasing with savory food was sufficient to cause the secretion, and that in highly sensitive animals even the noises or other events usually associated with feeding time were sufficient to excite it. In the case of a hungry animal, the mere approach of the attendant with food, or some other noise or action definitely associated with feeding time, was a sufficient excitant. The appetite juice when started was found to persist for some time after the stimulus causing it had been removed.

Carlson succeeded in confirming most of these observations in man. He noted, however, that the secretion produced by seeing or smelling or thinking

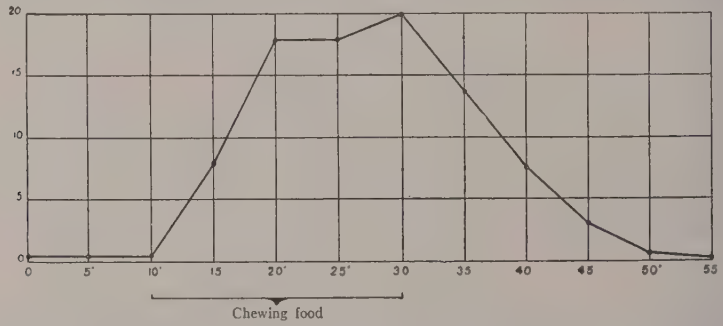

Fig. 327.—Typical curve of secretion of gastric juice collected at 5-minute intervals on mastication of palatable food for 20 minutes. The rise in secretion during the last 5 minutes of mastication is due to chewing the dessert (fruit) for which the person had great relish. (From Carlson.)

of food is much less than would be expected from Pavlov's observations on dogs. Even when his subject was hungry, Carlson did not observe that the bringing of a tray of savory food into the room caused any secretion of gastric juice. It is, of course, to be expected that the quantity of the psychic secretion will not be the same in different individuals. It has been observed by Pavlov, for example, to vary considerably in the case of dogs, and it is very likely that it will vary still more in man, with his more highly complicated nervous system. In no case could Carlson observe any secretion of gastric juice to be produced by having his patient chew on indifferent substances, or by stimulating the nerve endings in the mouth by substances other than those directly related to food.

In man the rate of secretion is proportional to palatability of the food, the smallest amount, during twenty minutes' mastication of palatable food, being 30 ml. and the largest 150 ml., in a series of 156 observations. A typical curve showing the amount of the secretion is given in Fig. 327. To construct this curve the gastric juice was collected during five-minute intervals while the man was chewing a meal of average composition and of his own choice. An interesting feature is that the secretion rate was highest in the last five-minute period,

this being the time during which the dessert was being taken, for which this man had a great relish. Quite clearly there was a direct relation between the rate of the secretion of the appetite juice and the palatability of the food. It will further be observed that it took only from fifteen to twenty minutes after discontinuing the chewing before the rate of secretion of juice returned to its original level.

The practical application of these facts in connection with the hygiene of diet and the feeding of patients during convalescence is obviously very great. However perfect in other regards a diet may be, it will probably fail to be digested at the proper rate unless it is taken with relish. Frequent feeding with favorite morsels is more likely to be followed by thorough digestion and assimilation than occasional stuffing with larger amounts. We see in these experiments an explanation of the well-established practice of starting a meal with something savory. An *hors d'oeuvre* is nothing more than a physiological stimulant to appetite. It is also interesting from a practical standpoint to observe that with those who have a keen relish for sweetmeats the taking of dessert has a real physiological significance, for, as in Carlson's patient, it stimulates toward the end of the meal a further secretion of the gastric juice, and thus insures a more rapid digestion of the food. Good cooking, it should be remembered, is really the first stage in digestion, and it is the only stage over which we can exercise voluntary control. Addition of water to the food within certain limits increases the secretion of gastric juice, and weak alcohol (0.5-10 per cent) is still more effective. Iced water and strong alcoholic drinks act as inhibitory agents.

There can be little doubt that in the normal individual this excitation of the gastric secretory process by the stimulation of receptors in the mouth, eyes, etc., without the actual presence of food in the stomach, is associated with the stimulation of certain cortical cells in the brain, and to this extent, therefore, justifies the use of the term *psychic secretion* in this connection. Zeliony,[127] however, has been able to show that the fundamental nervous mechanism can operate without concomitant stimulation of the cerebral cortex. Sham feeding of a decorticate dog resulted in secretion of gastric juice when the animal tasted food. From this it is evident that other than solely cortical responses are concerned. Because of this, Ivy[60] has suggested that the initial phase of gastric secretion be termed the *cephalic phase,* denoting that it is due to stimuli acting on sensory end-organs located in the head. Under this heading two types of responses may be distinguished: (1) those passing through the cerebral cortex (psychic), and (2) those involving the thalamus, midbrain or medulla, the afferent sensations being caused by the sight, smell and taste of food, chewing and swallowing quite probably playing the rôle of decreasing the threshold of the reflex arcs involved. The vagi are the efferent nerves concerned in conducting the impulses from the gastric secretory center or centers to the gastric glands.

The Gastric Phase of Gastric Secretion

When food is present in the stomach the gastric glands are stimulated to secrete. Pavlov investigated this phenomenon in dogs provided not only with a miniature stomach but with a simple fistula of the main stomach as well. The behavior of the secretion of gastric juice as a whole could be followed by collecting that which was secreted in the miniature stomach, for it was shown in control experiments, that this secretion runs strictly parallel with that in the main

stomach, being quantitatively a definite fraction of it—according to the size of the miniature stomach—and qualitatively identical. The miniature stomach, in other words, mirrors the events of secretion in the main stomach.

Local Mechanical Stimulation.—It was observed that when the animal was allowed to take the food into the main stomach by the mouth and esophagus, the secretion from the miniature stomach continued to flow until the process of gastric digestion had been completed, a result which was quite different from that obtained after sham feeding. The only possible explanation for this result is that the food in the stomach sets up secretion as a result of local stimulation. To investigate the nature of this local stimulation, whether mechanical or chemical, food and other substances were placed in the main stomach through the gastric fistula without the animal's knowledge, so as to avoid possible psychic stimulation, and the secretion observed from the miniature stomach. In these experiments of Pavlov, mechanical stimulation of the gastric mucosa by placing inert objects, such as a piece of sponge or sand in the stomach, were without effect; Pavlov therefore claimed that mere contact of the food with the gastric mucosa does not constitute an effective stimulus for gastric secretion. Beaumont had reported that rubbing the gastric mucosa of Alexis St. Martin's stomach resulted in the appearance of droplets of fluid on the surface of the stomach wall, presumably, in the light of our modern knowledge, at the points where each lumen of a tubular gland joined the lumen of the stomach cavity proper. Pavlov explained these observations of Beaumont as due to psychic secretion by some psychic stimulus received by Alexis St. Martin. It remained for Ivy and associates[60, 74] to demonstrate in a dog with an isolated stomach—where the esophagus was joined to the intestine, and the isolated stomach provided with a fistulous opening through the body wall—that mere contact alone of the mucosa with an inert object is not sufficient, but that if, at the same time there is a certain degree of stretching of the stomach wall associated with expansion of the viscus to accommodate the mass, the stimulus is an effective one. The experiments of Ivy in this connection constitute a closer approximation to the conditions which prevail in the normal organism. The student should realize that the empty stomach is not like a large empty bag, but rather a contracted viscus with the walls more or less in contact with each other; when swallowed food enters the stomach, the organ expands sufficiently to accommodate it and maintains a moderate tonic contraction on the contents, this pressure being altered at intervals as a result of the peristaltic waves which occur from time to time. This contact-plus-distention stimulus is effective in promoting the flow of gastric juice to aid in digestion of the mass.

The mechanical stimulus has been demonstrated to be effective not only in the pouch consisting of the isolated entire stomach, but in separate pouches consisting of the pyloric and the fundic portions. Curiously enough, distention of the pyloric pouch will stimulate secretion in the fundus. Mechanical stimuli are not effective if atropine has been given; they are also inhibited by the introduction of fats into the intestine (see "Gastric Chalone" below).

Local Chemical Stimulation.—It has been found that various foods show considerable difference in the degree to which they can promote the flow of juice. Water and egg white have only a slight effect; bread and starch in a dry state do not stimulate. On the other hand, when protein that has been partly

digested by means of pepsin and hydrochloric acid is introduced into the stomach, there is an immediate flow of secretion. A solution of commercial peptone has been found to be effective, which confirms the observations just cited. Evidently, certain foods, which in the swallowed state are ineffective, are first digested by the juice called forth in response to the so-called psychic stimuli, after which the products of this digestion further stimulate the secretory process. In this connection should be mentioned Pavlov's observation that commercial beef extract is effective in promoting the flow of gastric juice. This is an interesting finding, because previous studies of the nutritive value of this material—utilization of its nitrogen, etc.,—had led to the conclusion that it is valueless as a food. The discovery that this substance can promote the flow of gastric juice gives it a physiological use which may be desirable in certain individuals. This effect of meat extract is interesting also in connection with the practice of taking soup as a first or early stage of dining. It not only excites the flow of appetite juice but also serves as a direct stimulus of the gastric glands as soon as it reaches the stomach.

Pavlov attempted to evaluate for gastric digestion the psychic phase with and without the gastric phase. He placed weighed quantities of meat attached to threads in the stomach through a gastric fistula, and after some time removed them and determined by the difference in weights the extent to which digestion had occurred. It was found that when the appetite juice was excited by sham feeding at the same time that food was placed directly in the stomach, its digestion was much more rapid than in cases in which it was placed in the stomach without the animal's knowledge, as when he was asleep.

The nature of the mechanism by which the purely gastric phase of secretion takes place has received much attention by investigators. Popielski showed that this secretion still occurs after all the nerves proceeding to the stomach are cut, and concluded that the secretion must depend on a local reflex mediated through the nerve structures present in the walls of the stomach itself. Edkins[36] proposed a hormone mechanism substantially as follows: contact of acid and food substances with the mucosa of the pyloric portion of the stomach causes the elaboration and absorption into the blood of a hormone called gastrin which is carried to the glands of the fundus and excites them to activity. The chief facts that may be cited against this theory are (1) that a gastric secretin can be isolated from many animal as well as plant tissues, and therefore the gastrin of Edkins is not specific as to location in the pyloric mucosa, and probably not as to action or kind (Ivy), and (2) that attempts to demonstrate this hormone in the blood have met with failures or unsatisfactory results. Using a pouch of the entire stomach, Ivy and associates found that "meat or meat juice is the only one of the common food substances as yet used that stimulates gastric secretion when applied in amounts insufficient to involve stimulation by distention. Histamine and β-alanine are pure chemical substances that stimulate on local gastric application." In view of the fact that the intestinal phase of gastric secretion (see below) unquestionably involves a hormonal mechanism, one cannot say dogmatically, that such a mechanism is not involved in the purely gastric phase of secretion. It does appear proper to state, however, that the gastrin theory as enunciated by Edkins is inadequate. MacIntosh[80] has summarized considerable indirect evidence suggesting that histamine may be a step in the production of gastric juice when the vagus is stimulated. Sacks and col-

laborators[109] isolated histamine from the pyloric mucosa, and concluded that "histamine is the gastric hormone, or if not, there is no gastric hormone, or the gastric hormone has never been extracted from pyloric mucosa." More recently, however, Komarov[67] has reported the extraction from the pyloric mucosa of a protein-like substance having a specific secretagogue effect on the fundic glands. Komarov interpreted his observations as supporting the "gastrin" theory, and also suggested that "gastrin" may play some part in the intestinal phase of gastric secretion.

The Intestinal Phase of Gastric Secretion

Pavlov and others had observed that gastric secretion may be excited from the intestine, but it remained for Ivy and his associates to investigate this phenomenon and to elucidate its physiological significance. For this study they used dogs provided with Pavlov gastric pouches and isolated intestinal loops of the Thiry type, as well as animals in which the entire stomach had been isolated, the esophagus being joined to the duodenum. In the former group, the test substances could be placed in the intestine at will and the effect of this on the secretion of the miniature stomach observed; with the latter technique it was possible for the animal to ingest and swallow food in the usual manner but without passage of the food through the stomach; thus the purely gastric phase of secretion was eliminated. As an example of the most striking results obtained, we may cite the observations of Lim, Ivy and McCarthy[74] made on dogs with an isolated stomach. When cooked ground meat, bread, and milk are fed, the stomach pouch does not begin to secrete for from two to four hours. If the food is predigested with pancreatin or pepsin and hydrochloric acid, the entire stomach pouch secretes within an hour after feeding. The effect of drinking water seems to depend to a large extent on the degree of thirst and the time since the last meal, the shorter the time since the last meal, the greater being the stimulation. Mechanical distention of the intestine proves to be ineffective. Such observations support the view that the intestinal phase of gastric secretion is mediated by the absorption of secretin-like materials, products of digestion or specific hormones or both, from the intestine, and passage of them to the stomach by way of the blood stream. Finally, Ivy and Farrell succeeded in transplanting into the mammary gland a gastric pouch the original nervous and vascular connections of which had been severed. Such a transplanted pouch secretes a gastric juice containing free acid from two to six hours after a meal. This would seem to constitute proof that a humoral mechanism is concerned in gastric secretion. As Ivy himself points out, it does not, however, prove or disprove a hormone or a secretagogue mechanism. Ivy and his associates suggest that gastric secretion may in some way be related to an increased blood flow in the gastric vessels alone. Secretion is always associated with hyperemia of the stomach, and it is conceivable that the gastric glands are sensitive to an effective increase of blood flow through the organ.

It is not intended that this volume deal with clinical problems, but it will not be out of place to mention some of the practical implications of these researches on the intestinal phase of gastric secretion. For example, the hypernormal secretion that is associated with pylorospasm or pyloric stenosis can be adequately explained in the following manner (Ivy). The retention of food in the stomach leads to an augmentation of the gastric and intestinal phases

of gastric secretion. The gastric phase is augmented by an increased mechanical stimulation coincident with enhanced motility and blood flow, and by more prolonged action of secretagogues that are naturally present in such food substances as meat, or that result from digestion in the stomach. The intestinal phase is augmented because the chyme is more completely hydrolyzed, as the result of its retention in the stomach, so that when it is ejected into the duodenum it is more readily and rapidly digested. This more rapid digestion in the intestine means an increase in the concentration of secretagogues acting on or by way of the intestinal mucosa. Other factors known to play a rôle are the amount of diarrhea, the time of action of the chyme in the intestine, the amount of intestinal putrefaction, the degree of change of permeability of the intestinal mucosa, and the amount of passive as contrasted with active hyperemia. In other studies, Ivy[38] makes the suggestion that clinical cases of gastric hypersecretion should be examined for possible pancreatic dysfunction, because it has been shown that absence of pancreatic juice from the duodenum is associated with a more continuous secretion of gastric juice.

Gastric Chalone

Fat has been shown to exert a distinct inhibiting influence on the secretion of gastric juice; cream takes considerably longer to be digested than milk, and the presence of oil in the stomach delays the secretion of juice poured out on a subsequent meal of otherwise readily digestible food. Lim and associates[69] have succeeded in showing that this inhibitory action of fat is brought about through a humoral mechanism, the active agent passing into the blood stream when the fat comes in contact with the mucosa of the upper intestine. Since this agent is inhibitory in its action, it cannot be called a hormone, because this term signifies a stimulating agent; therefore the term *chalone* has been introduced as the name for an inhibitory substance elaborated in one tissue and passing by way of the blood stream to another tissue where it exerts its inhibitory action (see Chapter LXIX). Such an agent acting on the stomach might be called a gastric chalone. Greengard, Gray and Ivy[52] have extended the work in this field and concentrated the chalone sufficiently to be able to produce an experimental achlorhydria lasting from one to five hours. Their product, which they have called *enterogastrone,* was also found to cause some inhibition of gastric motility.

Quantity of Gastric Juice Secreted

In the light of what has already been presented concerning the various phases of gastric secretion, and the stimulating and inhibiting factors that may operate, it is evident that the amount of juice secreted in response to meals and in disease can be quite variable. According to Carlson, the total amount of gastric juice secreted in man on an average meal composed of meat, bread, vegetables, coffee and milk, and dessert, amounts to about 700 ml., being divided into 200 ml. in the first hour, 150 in the second, and 350 ml. during the third, fourth, and fifth hours. These figures were estimated partly on the basis of observations made on the man with the gastric fistula, and partly from the data supplied by Pavlov's observations on dogs. Estimates based on observations on dogs with the Pavlov miniature stomach are always subject to some reservations. More recently, Dragstedt and Ellis[33] have succeeded in preparing an isolated entire

stomach with intact vagus supply; such animals were observed to secrete from 1000-2600 ml. daily, the glands being able to secrete in response to stimuli even when the blood chloride concentration had been reduced to less than one-third of the normal value and there was extreme alkalosis. These authors express the belief that the failure to reabsorb the secreted gastric juice is the chief cause of death in high intestinal and pyloric obstruction, acute dilatation of the stomach, paralytic ileus in general peritonitis, gastrocolonic fistula, duodenal and gastric fistulas and profuse vomiting from other causes. The effective treatment for this loss of gastric juice was found to be simple replacement therapy by parenteral administration of large amounts of Ringer's solution daily.

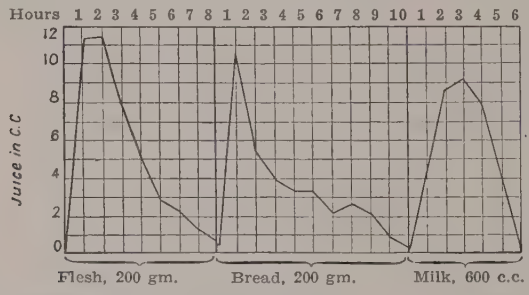

Fig. 328.—Cubic centimeters of gastric juice secreted after diets of meat, bread, and milk. (From Pavlov.)

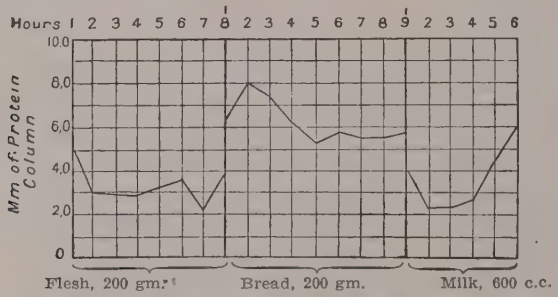

Fig. 329.—Digestive power of the juice, as measured by the length of the protein column digested in Mett's tubes, with diets of flesh, bread, and milk. (From Pavlov.)

The observations of Pavlov on the responses of gastric pouches of dogs to meat, bread, and milk have been widely quoted. They are interesting because they constitute evidence that the operation of the gastric secretory mechanism is not without some power of adaptation to the materials to be digested. In Figs. 328 and 329 are shown the results reported by Pavlov. It will be noted that the meal of meat called forth the secretion richest in acid, and the bread was most effective in stimulating the secretion of pepsin; also, the responses to bread and to milk were more sustained (compare curves in Fig. 329 for the fifth and succeeding hours) suggesting that these foods are more effective during the intestinal phase. These differences in responses with respect to acid and enzymes suggest that two separate secretory mechanisms may be involved, one concerned

in the elaboration and discharge of the hydrochloric acid, and the other in the secretion of pepsin and other enzymes. This is supported by the work of Babkin[5] and associates[114, 116, 117, 118] and Gilman and Cowgill[47] showing that the drug histamine stimulates only the acid-secreting mechanism. Whether this is true for man has been debated, but the carefully controlled studies of Toby[115] indicate that such is the case. This has naturally stimulated efforts to devise new gastric function tests useful in determining which of the two fundamental secretory processes may be deranged in pathological cases. The supposition that a satisfactory test might be based on the use of histamine and pilocarpine has proved to be erroneous because the amount of pilocarpine required to secure adequate stimulation of the pepsin-secreting mechanism is toxic. It has been found, however, that the hypoglycemia induced by injection of insulin is accompanied by stimulation of the vagal centers in the brain and a resultant secretion of gastric juice comparatively rich in pepsin.[6] Similarly, the vagal secretory centers can be stimulated by amino acids circulating in the blood[100, 101, 70] thus explaining in large measure the so-called intestinal phase of gastric secretion. This participation of the parasympathetic secretory innervation explains why the concentration of pepsin is higher in the gastric secretion of what Babkin calls the chemical phase[6] than in that obtained after histamine administration. The application of histamine and insulin in gastric function tests in man has been described by Babkin.[7]

THE INTESTINAL SECRETIONS

Pancreatic Juice

The secretion of pancreatic juice is studied by making a fistula of the duct, but, because of cicatrization, it is by no means easy to keep the fistula patulous. The secretion is almost absent during fasting, but starts in a few minutes after food is taken and increases in volume as more and more chyme enters the duodenum. In experimental animals the discharge of acid chyme from the stomach activates the secretin mechanism. The acidity of this chyme cannot, however, be the only excitatory cause for the secretion, for it occurs even in cases of achlorhydria where, possibly, it is due to the secretion of bile. The work of Mellanby[89] suggests very definitely that the presence in the intestine of bile, particularly the bile salts, promotes the flow of pancreatic juice, but the observations of Dragstedt and Woodbury[35] do not support this view.

McClure, Huntsinger and Fernald[84] have obtained samples of what they consider to be the bile, pancreatic juice, and gastric juice in the human duodenum following intraduodenal administration of pure foodstuffs and inorganic substances. From their study it was concluded that the concentrations of bile and pancreatic juice present in the duodenum vary with the type of stimulant administered, that the acid of gastric contents is not the essential factor in stimulating the secretion of concentrated bile and pancreatic juice thus contradicting the idea that acid is a specific and sole stimulant for the production of secretin, and finally, that cottonseed oil and peptone stimulate the liver and pancreas through secretagogic influences. Magnesium sulfate solution proved to be a much more potent stimulant of pancreatic secretion than hydrochloric acid.

This, as well as other work by McClure and associates also showed that fat is the most efficient stimulant of pancreatic enzymes and that the protein diges-

tion products are next in order, thus indicating a selective action on the processes of the pancreatic cell by which the different ferments are produced. In view of the good evidence for the existence of at least two separate secretory processes in the stomach (Gilman and Cowgill[47] and others[14, 116, 118, 120]) these findings of McClure et al., concerning the pancreas are not unintelligible. As indicated in the previous section, in which the adaptation of the gastric secretory response to the foods was discussed, we may consider that there is also some evidence supporting a similar adaptive capacity of the pancreas to the material presented for digestion. This is contrary to the older view, that the pancreatic juice remains very constant with regard to its content of the various ferments, the chief variation being with respect to the total amount secreted. It is obvious that the proof of this view must rest largely on the use of much more delicate analytical methods for measuring enzyme activity than those employed previously.

This contradiction of results obtained in animals with those yielded by human beings doubtless means that neither the acid-secretin mechanism nor the alternative possibilities should be taken as representing the entire truth to the exclusion of the other. It also indicates the importance of having at hand a satisfactory test for pancreatic secretory function which can be carried out easily under clinical conditions. If some dye or other readily detectable substance could be found, which upon injection is selectively eliminated by way of the pancreatic secretion, it might be made the basis of such a test. However, Crandall, Oldberg and Ivy[29] tested ninety dyes and could not find a single one that might be used.

The Bile

Composition.—Associated with the pancreatic juice in all its functions is the bile. When this fluid is prevented from entering the intestine, the digestive process becomes very imperfect, the absorption of fat being particularly interfered with (see page 975). Bile is also an excretory product, and its composition therefore is much more complex than that of the other digestive fluids. This varies considerably, however, according to the method of collection. Bile from the gallbladder after death contains much more solid material, particularly bile salts and mucin, than that collected from a fistula of the bile duct or gallbladder during life. These differences will be evident from Table CVI.

Table CVI

	BILE FROM	
	EXCISED GALLBLADDER	FISTULA OF COMMON BILE DUCT
100 parts contain—		
Water	86	97
Solids	14	3
Organic salts (bile salts)	9	0.9-1.8
Mucin and bile pigments	3	0.5
Cholesterol	0.2	0.06-0.16
Lecithin and fat	0.5-1.0	0.02-0.09
Inorganic salts	0.8	0.7-0.8

In general, it may be said that bile obtained from a fistula of the common bile duct in man contains only about 3 per cent of total solids, of which from one-fourth to one-half are inorganic, whereas bile obtained from a freshly excised gallbladder, and presumably, therefore, similar to the material occurring in the

viscus normally, contains from 10 to 20 per cent of total solids, of which only about one-twentieth are inorganic. The chief cause of this difference appears to be that when the bile goes to the intestine, a considerable proportion of its bile salts is reabsorbed into the portal blood and resecreted by the liver. Some of the difference may also be caused by the fact that absorption of water takes place from the gallbladder, and that mucin and possibly cholesterol are secreted by this organ. These striking differences between fistula and gallbladder bile are observed only when the common bile duct is occluded. If the bladder fistula is made with the common bile duct left open, some of the bile gains entry to the duodenum and therefore becomes reabsorbed and resecreted. It is well known that a fistula of the gallbladder in man closes after a time and the bile again takes its usual course along the bile duct into the duodenum.*

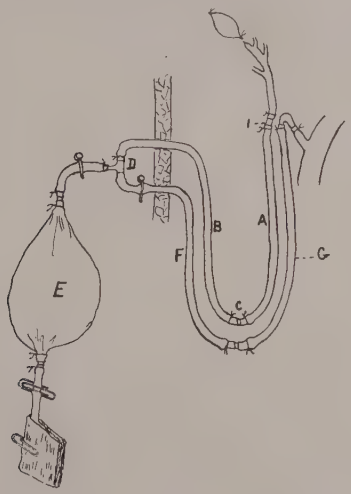

Fig.—330.—Diagram of altercursive intubation. A glass cannula (1) is inserted in the bile duct after ligating the cystic duct. It is connected by thin-walled rubber tubing, *A*, with thick-walled tubing, *B*, by means of a glass union, *C*. The thicker tubing passes through a narrow fistula in the abdominal wall and is attached to one limb of a T-piece, *D*, the central branch of which connects with a rubber bag, *E*. The remaining limb connects with another piece of thick tubing, *F*, going through a second fistula, and joined in the abdomen to thin tubing, *G*, attached to a cannula in the bile ducts near the duodenum. (From McMaster and Elman: J. Exper. Med. **41**: 529, 1925.)

Quantity of Bile Secreted and Factors Influencing It.—Interesting observations have been collected on the amount of the secretion from a fistula, both in man and in the lower animals. In man it is commonly stated that about 500 ml. of bile are secreted daily, the amount varying considerably during the different hours of the day. The secretion of bile is greatly reduced by hemorrhage. It is greater on a meat diet than on one of carbohydrates. It is reduced during starvation, but continues to be secreted up to the moment of death.

All estimates of bile flow based on observations of the discharge through a fistula, whether in man or animals, are subject to error depending on whether all bile is being diverted from the intestine or not. If it is, then the organism

*Further details concerning the chemistry of bile will be found on page 975.

cannot be maintained in a good state of health for very long; fat absorption is impaired, excessive intestinal putrefaction occurs, and anemia and other symptoms including even changes in the bones develop. Obviously, therefore, the use of a technique which permits observations of the flow during desired experimental intervals, with flow of the bile into the duodenum at other times, is desirable. The most suitable experimental procedure for accomplishing this seems to be that devised by Rous, McMaster and Elman[108] and called "altercursive intubation." A diagram showing the principles of this method is given in Fig. 330.

The gallbladder is tied off, a cannula introduced into the bile duct and connected with a piece of sterilized, flexible rubber tubing which is attached by a bent glass tube to a thicker piece of rubber tubing going through a stab fistula in the abdominal wall. The tube emerging from the fistula is connected with a T-piece, the central limb of which goes to a rubber bag for collecting the bile. The remaining limb of the T-piece is connected with tubing which goes through a second fistula in the abdominal wall to the duodenum. If the tubes be inserted with proper aseptic precautions, the animals can be kept in good health for several months, provided the bile is allowed to enter the intestine most of the time. It might be thought that the cannula in the bile ducts would soon become loose through necrosis of the walls beyond the ligature, but this is not the case. After a week or two, scar tissue closely embracing the cannula becomes developed around the duct. Even when the pressure of bile is raised to the maximum by obstruction of the bile ducts, no leakage occurs at this union of duct and cannula (Rous and McMaster and Elman[108]).

It has been found that the bile is always being secreted but in varying amounts under different conditions. For example, it becomes much lower during fasting and it also becomes greatly reduced if the bile is not allowed to reach the intestine. The secretion occurs quite independently of the nerves of the liver, for it persists after all of these have been cut. Normally the pressure in the bile ducts is low, but it increases considerably when these are obstructed and may rise to a height of about 300 mm. of bile when, however, the secretion suddenly ceases and reabsorption of bile takes place into the blood, resulting in jaundice. After taking a meal of meat or fat, the rate of secretion increases in about an hour and reaches a maximum in about five hours. Carbohydrate food, on the other hand, has no influence. The changes in the rate of secretion of bile therefore run more or less parallel with the secretion of the pancreatic juice. Reference has already been made to the conflicting observations of Mellanby,[89] and Dragstedt and Woodbury[35] on the question of a causal relationship of bile acids in the duodenum to the flow of pancreatic juice. There is no question, however, that pancreatic secretin promotes the flow of bile. When attempting to evaluate the numerous factors concerned in the stimulation of bile flow, the student should make a careful distinction between cholagogic activity—true stimulation of the secretory process in the liver—and factors which promote the discharge of bile by stimulation of the muscular wall of the gallbladder. Another distinction worthy of emphasis concerns the adequacy and accuracy of the experimental technique employed. Observations made on human beings with the tip of a swallowed tube in the duodenum cannot be as significant in elucidating the fundamental mechanisms as those made on animals under conditions where numerous important variables can be suitably controlled. Most of the substances which were formerly believed to be cholagogues have since been shown to act on the gallbladder musculature causing the viscus to contract, and not upon the secretory

process in the liver cells. Bile itself is probably the best of the known cholagogues; injection of it results in prompt elaboration and discharge of bile by the liver.

The Gallbladder.—In view of the anatomic arrangements it is evident that the bile collected from the common bile duct may be that newly formed by the liver cells or it may represent a discharge from the gallbladder. The prevalence of gallbladder disease in human beings makes it important to know as much as possible about the fundamental processes taking place in this organ. With regard to the functions of this viscus, Ivy summarizes the extensive literature on the subject as follows: *the gallbladder serves as a "factor of safety" in digestion,* and also as *a "factor of safety" in regulating the pressure in the biliary passages.* Bile is secreted practically continuously, but because of the sphincter located at the end of the common bile duct, this bile cannot flow at all times into the duodenum; it may therefore be stored in the gallbladder and thus be made available for intestinal digestive processes when required. The proved ability of the gallbladder to concentrate the bile means that its storage capacity is increased correspondingly. The facts that the ingestion of fatty foods brings about evacuation of the gallbladder more rapidly and completely than other foods, and that bile salts play an important rôle in the digestion and absorption of fats, in the promotion of bile formation, and in favoring intestinal motility, all support this view as to the function of this organ. The stored bile, according to this theory, is analogous to the psychic or "ignition" gastric juice, and was called "ignition" bile by Pavlov. "But, just as 'ignition (psychic) gastric juice' is not essential for adequate digestion, 'ignition bile' may not be essential. As the psychic secretion of gastric juice is very probably one of the 'factors of safety' in digestion, gallbladder bile may be viewed as a 'factor of safety' in digestion, other factors being able to compensate to an adequate degree for its absence after cholecystectomy" (Ivy). The function of this viscus in the regulation of pressure in the biliary passages is of considerable importance, particularly in those species like man, which are provided with a powerful sphincter situated at the end of the common bile duct and capable of sudden closure. The gallbladder functions as an elastic bag connected to a system of tubes. Being able to concentrate bile rapidly and markedly, its effectiveness as an elastic reservoir is thereby increased. It may be described as "a pressure regulatory and storage reservoir of small volume but of large capacity," one that "is able to provide for varying rate of bile formation and for the exigency that the bile may not be able to escape into the intestine because of the resistance of the choledochoduodenal mechanism. Thus, the secretory activity of the liver may continue unhampered by the inhibitory effects of high intraduct pressures for a period of hours."* The fact that not all species are provided with a gallbladder is not as serious an argument against these views as appears on first thought, because in species without the viscus, the resistance encountered by bile at the end of the common bile duct is small, and the passage of bile is practically continuous. When the gallbladder is removed, it is found that the ducts dilate or that the sphincter mechanism at the choledochoduodenal junction relaxes in some manner.

Among the important factors found to cause emptying of the gallbladder is the presence of certain foods in the intestine. Fat and fatty acids are most

*Ivy: Physiol. Rev. 14: 85, 1934.

effective, proteins (meat) rank next, and carbohydrates are least potent; these agents produce this action through a humoral mechanism, for they are effective after all the nerves have been cut. Ivy and Oldberg[65] have succeeded in preparing extracts of the duodenal mucosa which cause contractions of the gallbladder on intravenous injection, and have called this hormone "cholecystokinin." Chemically, it appears to be closely related to pancreatic secretin. The contractions of the gallbladder may also be brought about in experimental animals through stimulation of nerves, the vagus conveying augmentor and the sympathetic, inhibitory impulses, but it is questionable whether the "normal" contraction and evacuation of the viscus involves an extrinsic nervous mechanism, because of the ease with which fat placed in the duodenum can bring about emptying of the completely denervated gallbladder. The peculiarities of the reaction of the gallbladder to foods have been made the basis of certain practical suggestions for the clinic. The individual who has a tendency to formation of gallstones would do well to eat only a few meals a day, at least one of which contains an appreciable amount of fat, and thus supply at least once a day a vigorous stimulus to gallbladder emptying with the result that stones still small enough to be passed without pain are forced out. If many meals are taken at frequent intervals the stimuli for emptying are operating more or less continuously and the viscus at no time is given an unusually powerful one. On the other hand, in a patient with a fistula, healing of the fistula is improved by avoiding the continual oozing of bile, and this may be accomplished by feeding frequently with the result that the choledochoduodenal sphincter is kept open and bile flows readily into the intestine.

The discovery by Graham et al., that various nontoxic halogenized dyes, when injected, are excreted by way of the bile, combined with the fact that the concentrated dye in the gallbladder is opaque to the x-rays, has led to the technique of *cholecystography* for obtaining shadows of the gallbladder and biliary passages for diagnostic use in clinical medicine. Tetraiodophenolphthalein has been found to be particularly useful in this connection.

Intestinal Juice

The secretion of intestinal juice, or succus entericus, can obviously be studied only after isolating portions of the intestine and connecting them with fistulas of the abdominal wall. It appears here again that both a nervous and a hormone mechanism exist. Mechanical stimulation of the mucous membrane causes an immediate outflow of intestinal juice, the purpose of which under normal conditions is to assist in maintaining the fluidity of the bowel contents. This mechanically evoked juice does not contain any enterokinase and only small amounts of the other enzymes. Further evidence for nervous control of the secretion of intestinal juice has been obtained by isolating three pouches of intestine between ligatures, and then denervating the central pouch by carefully cutting all the nerves without wounding the blood vessels. On returning the pouches to the abdomen and leaving them several hours, it has been found that the middle pouch becomes distended with secretion, whereas the two end pouches remain empty. If the pouches are left for several days in the abdomen, however, the secretion from the denervated portion disappears again. A possible explanation of the result is that the nerves under normal conditions convey impulses to

the intestinal glands, which tonically inhibit their activity. This phenomenon is very much like the paralytic secretion of saliva (see page 894).

The existence of hormone control is best evidenced by the behavior of transplanted loops of intestine, such as those prepared by Nasset, Pierce and Murlin;[97] the presence of food in the digestive tract was accompanied by an increased rate of secretion by the loop not only of fluid but of the enzymes as well. The enzymes found in the intestinal juice are maltase, lactase, sucrase, erepsin, enterokinase, nuclease, phosphatase, and lipase. Nasset[95] has prepared from the small and large intestines of several animal species extracts shown to be potent excitants of the glands of the small intestine. These extracts were free from histamine, evidenced by a lack of influence on blood pressure, and from secretin, shown by their failure to excite the pancreas. *Enterocrinin* (intestinal secretagogue) has been proposed as a name for this hormone.

Other agents which have been demonstrated to promote the flow of intestinal secretion are histamine, pilocarpine, and the crystalline preparation of secretin isolated by Agren[1] (see page 896).

CHAPTER LXII

MECHANICAL FACTORS OF DIGESTION

MASTICATION, DEGLUTITION, VOMITING

In addition to the secretion of digestive juices purely mechanical factors operate in the alimentary tract in the handling of food. Many foods require some degree of comminution to reduce them to a size compatible with swallowing. It is necessary for the ingested material to pass through the thorax in order to reach the stomach and intestines. After digestion has occurred in the stomach the food must be passed on to the intestine. Sometimes it is important that the swallowed substance be prevented from leaving the stomach, that it be rejected entirely, and in order to meet this situation the mechanism of vomiting operates. Physical mechanisms are required for these processes. It is now our purpose to describe these mechanical factors of digestion.

Mastication

This process occurs in the mouth through the cooperation of the teeth and the muscles of the jaws. By the movements of the lower jaw on the upper, the two rows of teeth come together so as to serve for biting and crushing the food. The resulting comminution of the food forms the first mechanical step in digestion. The up-and-down motion of the lower jaw results in biting by the incisors, and after the mouthful has been taken, the side-to-side movements enable the grinding teeth to crush and break it up into fragments of the proper size for swallowing. The most suitable size of the mouthful is about 5 ml., but this varies greatly with habit. After mastication, the mass weighs from 3.2 to 6.5 Gm., about one-fourth of this weight being due to saliva. The food is now a semifluid mush containing particles which are usually less than 2 mm. in diameter. Some, however, may measure 7 or even 12 mm.

Determination of the proper degree of fineness of the food is a function of the tongue, gums, and cheek, for which purpose the mucous membrane covering them is supplied with very sensitive touch nerve endings. The sensitiveness of the tongue, etc., in this regard explains why an object which can scarcely be felt by the fingers seems to be quite large in the mouth. If some particles of food that are too large for swallowing happen to be carried backward in the mouth, the tongue returns them for further mastication.

The saliva assists in mastication in several ways: (1) by dissolving some of the food constituents; (2) by partly digesting some of the starch; (3) by softening the mass of food so that it is more readily crushed; and (4) by covering the bolus with mucus so as to make it more readily transferable from place to place. The composition of saliva varies according to the nature of the food (page 902). In some animals, such as the cat and the dog, mastication is unimportant, coating of the food with saliva being practically the only change which it undergoes in the mouth, in man the ability to bolt the food can readily be acquired, not, however, without some detriment to the efficiency of digestion as a whole. Soft

starchy food is little chewed, the length of time required for the mastication of other foods depending mainly on their nature, but also to a certain degree on the appetite and on the size of the mouthful.

It cannot be too strongly insisted upon that the act of mastication is of far more importance than merely to break up and prepare the food for swallowing. It causes the food to be moved about in the mouth so as to develop its full effect on the taste buds; the crushing also releases odors which stimulate the olfactory epithelium. On these stimuli depend the satisfaction and pleasure of eating, which in turn initiate the process of gastric digestion (see page 905).

The benefit to digestion as a whole of a large secretion of saliva, brought about by persistent chewing, has been assumed by some to be much greater than it really is, and there has existed, and indeed may still exist, a school of faddists who, by deliberately chewing far beyond the necessary time, imagine themselves to thrive better on less food than those who occupy their time with more profitable pursuits. These faddists usually assume that prolonged chewing insures more complete digestion of food by the saliva. In this connection it is pertinent to remark that salivary digestion can and does take place in the normal stomach for as much as a half-hour before the concentration and mixture with the acid of the gastric juice inactivates the ptyalin. This is due to the fact that each swallowed bolus tends to be placed in the center of the mass already in the stomach (see page 935), and some time is required before it comes to be the outer layer of the mass where it is in contact with the acid gastric secretion. In view of this fact, long-continued chewing would seem to be of no advantage.

Deglutition or Swallowing

This process is quite complicated and is best understood as occurring in three stages. The *first stage* is voluntary in nature and consists in the manipulation of the food in the mouth and preparation of it for passage into the upper part of the esophagus. After being masticated the food is rolled up into a bolus by the action of the tongue against the palate, and after being lubricated by saliva is moved, by elevation of the front of the tongue, toward the back of the mouth. It is very difficult or impossible to swallow dry material. The importance of proper flow of saliva and its admixture with the dry substance is thus emphasized. Psychic inhibition of salivary secretion as a result of great emotional stress, with a resultant inability to swallow a dry morsel, was made the basis of the so-called "trial by ordeal" in the Middle Ages, where an individual charged with a crime was forced to attempt to swallow dry flour or similar material. Interesting details of this process by which the morsel of food is manipulated in the mouth by the tongue are presented in Fig. 331, taken from the observations of Mosher.[94] It will be noticed that by approximation of the tip of the tongue to the roof of the mouth, escape of the bolus through the oral opening is prevented; also, the sudden movement backward of the posterior half and base of the tongue furnishes a propulsive force useful in driving the bolus through the pharynx into the upper end of the esophagus, the next stage of the process. Fig. 332 indicates the mechanism of swallowing as set forth by Barclay,[11] who believes that the movement of the tongue just mentioned is not the only force operating to insure passage of the bolus through the pharynx, but that suction plays a role, the negative pressure arising as a result of the elevation of the larynx and the back-

ward movement of the tongue. *Dysphagia in the first stage* is brought about by any factor which interferes with these manipulative movements of the tongue, or the failure to secure proper concomitant secretion of saliva.

The *second stage of swallowing,* a purely involuntary process, is essentially a complicated coordinated reflex act. It involves the passage of the bolus from the back of the mouth through the pharynx into the esophagus. It begins when the bolus, by stimulating sensory nerve endings (Fig. 333), acts on nerve centers located in the medulla oblongata so as to cause a coordinated series of contrac-

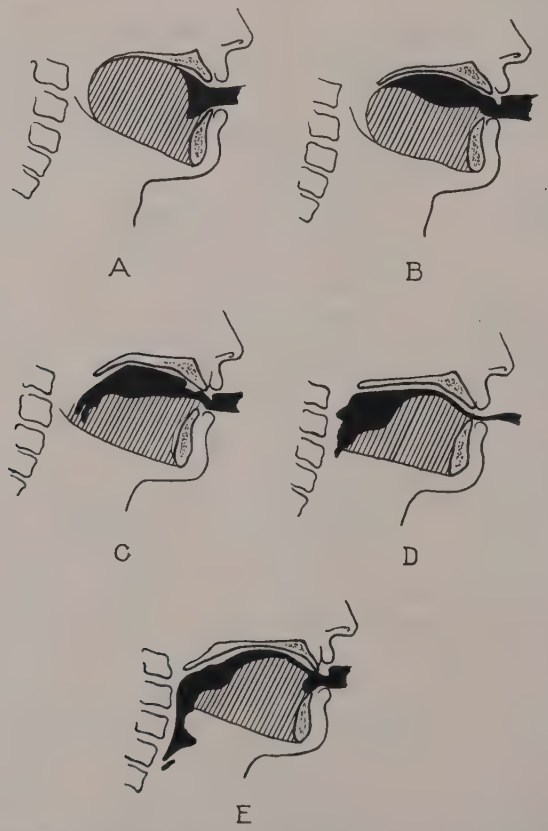

Fig. 331.—Drawings of a series of retouched tracings of x-ray films showing the movements of the tongue in swallowing.

A. The tip of the tongue is depressed and the barium accumulates above and in front of the tip of the tongue and behind the teeth.

B. The tip of the tongue comes up and the dorsum of the tongue sinks.

C. The tip of the tongue remains up. The dorsum and the base sink. The dorsum of the tongue becomes an inclined plane which slants downward from before backward.

D. The anterior half of the tongue rises as a globular mass to the roof of the mouth. The base of the tongue is depressed further. The individual now has the maximum mouthful.

E. The anterior half of the tongue remains at the roof of the mouth. The posterior half and the base of the tongue rise and are seen under the fluoroscope to shoot suddenly backward, driving the barium quickly down the pharynx. (Redrawn from H. P. Mosher: Laryngoscope 37: 235, 1927.)

tions of the muscles of the pharynx and larynx and an inhibition for a moment of the respiratory center. At the beginning of the second stage there is a slight inspiratory contraction of the diaphragm—the so-called respiration of swallowing—and the mylohyoid muscles quickly contract, with the result that the bolus

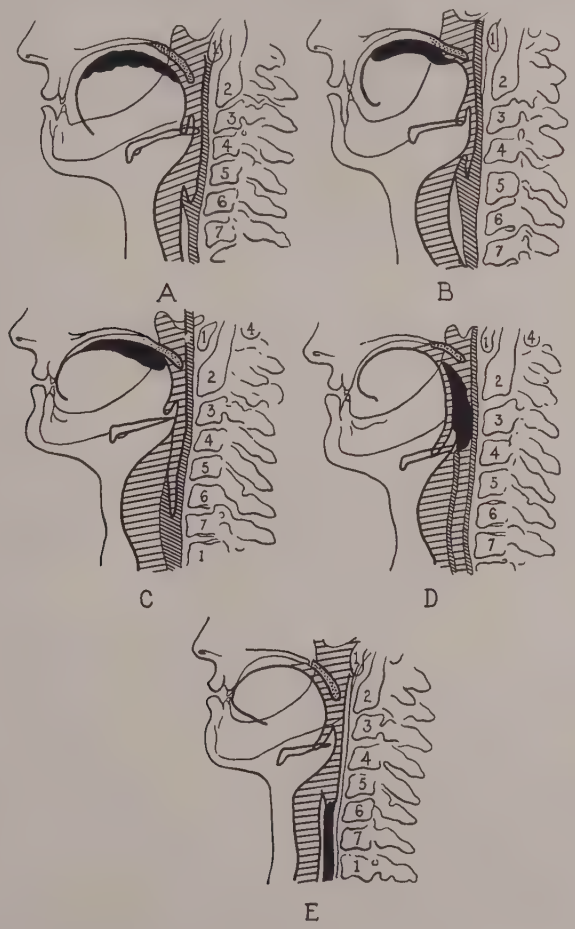

Fig. 332.—Stages in the swallowing process.

A. Before swallowing; bolus lies in the curve of the tongue. The figure shows the beginning of the act of swallowing. The bolus is compressed and the soft palate thrown against the posterior wall. The larynx is rising with the hyoid and the pharynx is narrowed.

B. Bolus compressed, nose closed off, larynx raised, pharynx and upper larynx obliterated.

C. Pharynx opening up, laryngeal pharynx drawn up to epiglottic position. Esophagus is an open tube and upper larynx is open again.

D. Pharynx open; laryngeal pharynx is in epiglottic position and food drops over epiglottis into open esophagus. Food caught on the epiglottis is deflected down aryepiglottic folds.

E. Laryngeal pharynx and esophagus drop with contents back to normal position. Bolus looks like a big drop in space. (After Barclay from Alvarez: *An Introduction to Gastro-Enterology,* New York, 1940, Paul B. Hoeber, Inc.)

passes rapidly between the pillars of the fauces into the upper end of the esophagus. At the same time the larynx is slightly elevated.

The movements thus brought about are designed to insure that the bolus shall pass into the upper end of the esophagus and not through any of the other passages which open into the pharynx, such as the nares, the larynx, and the chamber of the mouth. The soft palate becomes elevated, thus closing the opening into the nose; the posterior pillars of the fauces approximate so as to shut off the mouth cavity; and, in about a tenth of a second after the mylohyoid has contracted, the larynx is further pulled upward and forward under the root of

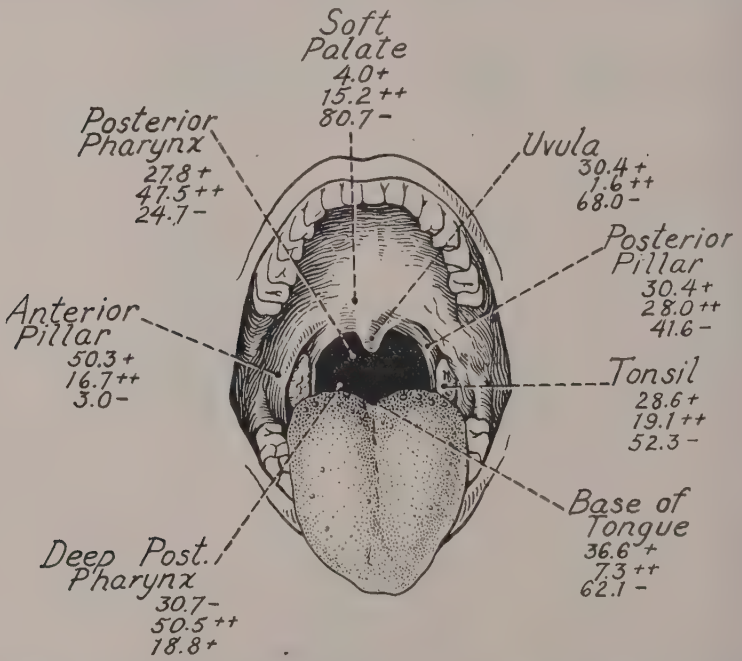

Fig. 333.—A drawing of mouth, tongue, and pharynx showing the positions of the several trigger zones, stimulation of which reflexly produces swallowing. The plus (+) sign indicates a swallowing reflex in response to a light stimulus over a small area. The double plus (++) sign indicates a swallowing reflex which occurred only in response to a stronger stimulation over a larger area. The minus (–) sign indicates no response. The figures represent percentages of results obtained in a study of 126 individuals. (Redrawn from Pommerenke: Am. J. Physiol. 84: 36, 1928.)

the tongue, which by being pulled backward becomes banked up over the laryngeal opening. This pulling up of the larynx brings its upper opening near to the lower half of the dorsal side of the epiglottis, and the laryngeal pharynx is pulled up with it. Swallowing is impossible unless the larynx is free to move. As a further safeguard against the entry of food into the air passages, the laryngeal opening is narrowed by approximation of the true and the false vocal cords. This is due to rotation of the arytenoid cartilages forward and inward so that the laryngeal opening becomes slitlike.

So far the force which propels the bolus is mainly the contraction of the mylohyoid, assisted by the movements of the root of the tongue. Now, however, a suction pressure is created in the pharynx by the larynx dropping and the tongue moving forward. This occurs while the pharynx is still pulled up so that the bolus readily enters it, after which it drops back to the normal position, thus allowing the larynx to open again. The bolus now readily enters the esophagus, which has become dilated on account of a reflex inhibition of the constrictor muscles of its upper end. This complicated coordinated movement of the second stage of swallowing involves, therefore, reciprocal action of various groups of muscles: inhibition of the respiratory muscles and of those that constrict the esophagus, and stimulation of those that elevate the palate, the root of the tongue, and the larynx. The entire process requires only about one-fifth of a second for its completion.

Dysphagia in the second stage may occur as the result of the action of any factor which interferes with this complicated reflex. Thus, the application of a local anesthetic to the appropriate receptors in the back of the mouth and pharynx will prevent the passage of nerve impulses to the swallowing center. Likewise, lesions involving the nerve paths through which the reflex is mediated can cause dysphagia in the second stage, and this dysphagia becomes a diagnostic sign of importance to the neurologist.

During the *third stage of deglutition* the swallowed food passes along the esophagus and through the cardiac sphincter into the stomach. The upper third of the esophagus contains cross-striated muscle fibers capable of rapid contraction; approximately the lower third is provided with smooth muscle only; the intermediate region contains a mixture of both types of muscle. The mechanism by which the food passes through the esophagus depends to some extent on the physical consistency of the food. The primary wave of peristalsis results from the pharyngeal stimulation and, in the case of a solid bolus that more or less fills the esophagus, there is produced a so-called secondary peristalsis due to local stimulation of the esophageal wall. The peristaltic wave travels down the esophagus in man at such a rate that it reaches the cardiac sphincter in about five or six seconds. On arriving here the cardiac sphincter, ordinarily contracted, relaxes for a moment so that the bolus passes into the stomach. In many animals, including man and the cat, the peristaltic waves travel much more rapidly in the upper part of the esophagus than lower down because of differences in the nature of the muscular coat. The purpose of more rapid movement in the upper part is no doubt that the bolus may be hurried past the regions where, by distending the esophagus, it might interfere with the function of neighboring structures, such as the heart. In other animals, as the dog, the muscular fiber is striated all along the esophagus, and the bolus of food correspondingly travels at a uniform, quick rate all the way. It takes only about four seconds for the bolus to reach the stomach of the dog.

Research has demonstrated that the harmonious sequence of contractions involved in the passage of the peristaltic wave along the esophagus depends upon an extrinsic nervous mechanism and not on a simple conduction of contractions from one portion of the muscular wall to another. The peristaltic wave of the upper part of the esophagus in the cat, and presumably in man, is transmitted by the esophageal branches of the vagus nerves. If these are severed, but the muscular coats are left intact, the esophagus becomes dilated above the level of the

section and contracted below, and no peristaltic wave can pass along it; on the other hand, the muscular coat may be severed (by crushing, etc.), but the peristaltic wave will continue to travel, provided no damage has been done to the nerves.

In the lower part of the esophagus, however, the wave of peristalsis, like that of the intestines, travels independently of extrinsic nerves. This has been observed in animals in which all of the extrinsic nerves have been cut some time previously. This difference between the upper and the lower portions is associated with the difference in the nature of the muscular fibers above noted.

The propagation of the wave by the nerves in the upper part of the esophagus indicates that the second stage and the first part of the third stage of swallowing must depend on impulses which come from the centers from which arise the nerve fibers to the pharynx, the larynx, and the upper levels of the esophagus. The discharges from the local centers are coordinated by a higher *swallowing center* situated in the medulla just above that of respiration, the afferent stimuli to which come from the pharynx by the fifth, superior laryngeal, and vagus nerves. The exact location of the sensory areas whose stimulation is most effective in initiating the swallowing reflex varies considerably in different animals. In man it is probably at the entrance to the pharynx; in the dog it is on the posterior wall. A foreign body placed directly in the upper portion of the esophagus of man has been observed to remain stationary until the individual made a swallowing movement. The afferent fibers in the glossopharyngeal nerve exercise a powerful *inhibitory* influence on the swallowing center as well as on that of respiration. Thus, if swallowing movements are excited by stimulating the central end of the superior laryngeal nerve, they can be instantly inhibited by simultaneously stimulating the glossopharyngeal, and the respiratory movements stop in whatever position they may be at the time. When the glossopharyngeal nerves are cut, the esophagus enters into a condition of tonic contraction, which may last a few days. This shows that the inhibiting impulses are acting continuously.

This inhibition of the esophagus is indeed a most important part of the process when liquid or semiliquid food is swallowed. By contraction of the mylohyoid muscle, fluids are quickly shot down the dilated esophagus, at the lower end of which, on account of the closure of the cardiac sphincter, they accumulate until the arrival of the peristaltic wave which has meanwhile been set up by stimulation of the pharynx. As the peristaltic wave approaches the cardia the sphincter becomes inhibited, allowing the fluids to be passed into the stomach. If the swallowing is immediately repeated, the esophagus remains dilated until peristalsis is inhibited and the fluid collects above the closed cardiac sphincter until the last mouthful is taken when the peristaltic wave passes over the esophagus and sweeps the contents through the sphincter which is at the same time relaxed. When a series of swallows in rapid succession, as in drinking, is made, the cardiac sphincter may remain inhibited throughout, so that the fluid passes directly into the stomach unassisted by the peristaltic wave. This mechanism does not of course operate when swallowed fluid must be raised against gravity as, for example, in the circus performer who takes a drink while standing on his head, or in the giraffe. In such cases, it is necessary for the liquid bolus to be moved along the esophagus by the peristaltic wave.

In addition to the reflex mechanism just described, it can be shown that secondary reflexes exist, and these are brought into play by stimulation of sensory fibers in the esophageal wall. These are of particular value when the primary reflex of swallowing is weak and results merely in forcing the food into the upper end of the esophagus. These reflexes are called forth with vigor whenever there is an obstruction of the esophagus: the presence of material above the obstruction results in a series of increasingly vigorous contractions, that operate to force the bolus against and through the obstruction if possible. Such contractions may be associated with considerable pain. In these secondary reflexes as well, the vagus nerve forms part of the nerve path involved. Sometimes a bolus is swallowed without having been sufficiently lubricated with saliva as, for example, in an individual who eats during a period of emotional stress and who therefore has some degree of psychic inhibition of salivary secretion. By vigorous effort he succeeds in forcing himself to swallow a dry bolus. Because of insufficient lubrication, the mass passes along the esophagus more slowly than usual with the result that it reaches the cardiac sphincter after it has opened and then closed. The bolus is then forced against the closed sphincter by the secondary reflexes in an attempt to pass the obstruction. During this period the individual may be conscious of considerable distress. After a short interval, however, the cardiac sphincter relaxes, the bolus is passed into the stomach, and the pain vanishes.

Dysphagia in the third stage results from any interference in the passage of the bolus through the esophagus. This may be due to purely mechanical causes, such as an enlarged thyroid gland, an aneurysm, neoplasms, traction exerted by scar tissue pulling the esophagus to one side thus rendering the passage more difficult, and cicatricial stenosis following ulceration due to corrosive poisons. It is obvious that dysphagia may also be the result of lesions involving the nerve paths through which the fundamental reflex is mediated.

The Cardiac Sphincter

The passage between the esophagus and the stomach is guarded by the cardiac sphincter or cardia. This exhibits a slight degree of tonus, superimposed upon which, from time to time, are rhythmic alternations of contraction and relaxation. This tonus is never very pronounced. In man it is said that a water pressure of 2 to 7 cm. applied to the esophageal side of the sphincter will drive air or water into the stomach, this pressure being less than that of a column of fluid filling the thoracic esophagus in the erect position. During repeated deglutition the tonus becomes less and less marked, and after a number of swallows the sphincter may become completely relaxed. When this relaxation disappears, however, the sphincter becomes more contracted than usual and remains so for a longer time.

The tonic condition of the sphincter is controlled by the vagus nerve, stimulation of which causes relaxation with an after-effect of strong contraction. The experiments of Brücke and Stern[16] may be cited as showing that the vagus carries inhibitory adrenergic fibers to the sphincter in contrast to the splanchnics which supply excitatory cholinergic fibers, stimulation of which can result in cardiospasm. Mechanical or chemical stimulation of the lower end of the esophagus increases the tonus of the sphincter. Forcing of the sphincter from the stomach side requires a higher pressure than from the esophageal. Eructa-

tion of gas, for example, does not take place until intragastric pressure has risen to about 25 cm. of water. In deep anesthesia, however, intragastric pressure may rise considerably higher without forcing the sphincter.

In animals fed with starch paste impregnated with insoluble salts of bismuth or barium and then examined by means of the x-rays, variations in degree of tone of the sphincter have been observed to be responsible for *occasional regurgitation of some of the gastric contents* into the esophagus up to the level of the heart and even to the base of the neck. The presence of the gastric contents in the esophagus starts a peristaltic wave, which pushes the material back again into the stomach. This peristaltic wave starts in the absence of any other phases of the deglutition process, indicating that it has been excited by the presence of the material in the esophagus itself, and belongs, therefore, to the lower order of peristaltic wave, as seen in the intestines but not in the upper half of the esophagus. The secondary reflexes described in the preceding section are doubtless involved here. Regurgitation of food into the esophagus occurs only when the intragastric pressure is fairly high. It may occur during a period of twenty to thirty minutes after a meal is taken, and disappear when the tonus of the sphincter becomes increased as a result of the presence in the gastric contents of free hydrochloric acid.

By listening with a stethoscope to the *sounds caused by swallowing,* it is usual to find that when a solid bolus is swallowed only one sound is heard, but with a liquid food there are two, one at the upper end due to the rush of the fluid and air, and the other at the lower end (heard over the epigastrium), four or five seconds later, due to the arrival of the peristaltic wave with the accompanying opening of the cardiac sphincter and the escape of the fluid and air into the stomach. Sometimes, when the person is in the horizontal position, this second sound may be broken up into several, indicating that, unassisted by gravity, the fluid does not so readily pass through the sphincter. The x-ray shadow yields results in conformity with the above. After swallowing milk and bismuth, for example, the shadow falls quickly to the lower end of the esophagus and then passes slowly into the stomach. When the passage of a solid bolus is watched by the x-ray method, its rate of descent will be found to depend on whether or not it is well lubricated with saliva; a well-lubricated bolus takes from eight to eighteen seconds.

Vomiting

The act of vomiting in the adult is a complex reflex act involving the muscles of the abdominal wall, the diaphragm, and the stomach itself. The early work of Magendie (1813) on this problem is most interesting. This investigator removed the stomach and substituted for it a bladder filled with fluid; injection of an emetic was followed by a typical vomiting movement resulting in ejaculation of the contents of the bladder. This, together with the fact, that vomiting cannot be brought about in a curarized animal owing to paralysis of the muscles of the abdominal wall by the drug (Gianuzzi) seemed to prove that the stomach itself plays a purely passive rôle during the act. X-ray studies have since demonstrated that such is not quite the case, but that the stomach by certain contractions does assist in the vomiting act.

Vomiting is usually preceded by a feeling of sickness or nausea, and is initiated by a very active secretion of saliva. The saliva, mixed with air, accumu-

lates to a considerable extent at the lower end of the esophagus, which it distends. A forced inspiration is now made, during the first stage of which the glottis is open so that the air enters the lungs, but later the glottis closes so that the inspired air is sucked into the esophagus which, already somewhat distended by saliva, now becomes markedly so. In the initial stages of the vomiting act a vigorous contraction occurs in the stomach at the incisura angularis; this separates the pyloric antrum from the fundic region which becomes a flaccid bag. The abdominal muscles then contract so as to compress the stomach against the diaphragm which is also contracted and, simultaneously, the cardiac sphincter relaxes, the head is held forward, and the contents of the stomach are ejected through the previously distended esophagus. After the contents of the stomach itself have been evacuated, the pyloric sphincter may also relax and permit the contents (bile, etc.) of the duodenum to be vomited. There are two important effects of the contraction of the diaphragm: the pressure brought to bear on the stomach in conjunction with the contractions of the abdominal muscles is greater, and the intrathoracic pressure is reduced thus allowing the esophagus to enlarge. It is an interesting fact that during the vomiting act there are no antiperistaltic contractions. Vomiting in the infant appears to be a more passive affair due most often to too great distention of the stomach by fluid, milk, for example.

Nervous Control of Vomiting.—The act of vomiting is controlled by a center located in the medulla, and the afferent fibers to this center may come from many different regions of the body. Perhaps the most potent of them come from the sensory nerve endings of the fauces and pharynx. This explains the tendency to vomit when the mucosa of this region is mechanically stimulated. Other afferent impulses come from the mucosa of the stomach itself, and these are stimulated by *emetics,* important among which are strong salt solutions, mustard water, and zinc sulfate. Certain other emetics, particularly apomorphine and to a lesser degree tartar emetic, act on the vomiting center itself, and can therefore operate when given subcutaneously. Afferent impulses causing vomiting may also arise from the abdominal viscera. Thus is explained the vomiting which occurs in strangulated hernia, and in other irritative lesions involving this region. X-ray observations have been made on the movements of the stomach of cats after the administration of apomorphine (Cannon). The first change noted is an inhibition of the cardiac end of the stomach, which becomes a perfectly flaccid bag. About the midregion of the organ, deeper contractions then start up, which sweep toward the pylorus, each contraction stopping as a deep ring at the beginning of the vestibule, while a slighter wave continues. A very strong contraction at the incisura angularis finally develops and completely divides the gastric cavity into two parts. On the left of this constriction the stomach remains completely relaxed, but at the right of it waves continue running over the vestibule. It is while the stomach is in this condition that the sudden contraction of the diaphragm and abdominal muscles ejects the cardiac contents into the relaxed esophagus. As these jerky contractions are continued, the gastric walls seem to reacquire their tone. Afferent impulses from the duodenal mucosa are even more potent for the initiation of the vomiting reflex than are impulses arising in the stomach itself (see Hatcher).

Pathological Vomiting.—Continuous or nearly continuous vomiting may occur in certain individuals who have established a vomiting habit because of the

ease with which the reflex may be conditioned. In such persons very slight stimuli may provoke a paroxysm of vomiting. Conditions such as the continuous vomiting of pregnancy, for example, belong in a different category; they must be due to the persistence of some etiologic factor. In the case of the illustration just cited, this factor may be continuous afferent impulses arising in the uterus and stimulating the center by reflex excitation. In view of what is known concerning the mechanism of vomiting, it is conceivable that such a condition may be due to a metabolic agent in the blood acting more or less continuously on the vomiting center. Some of the results of continuous vomiting are malnutrition of greater or lesser degree, constipation due to the partial starvation, and a degree of alkalosis varying with the extent to which the vomitus contains intestinal fluids as well as gastric secretion

CHAPTER LXIII

MECHANICAL FACTORS OF DIGESTION (Cont'd)

THE MOVEMENTS OF THE STOMACH

The Character of the Movements.—Even from the earliest days it has been recognized that the stomach performs two important functions: (1) receiving the swallowed food and then discharging it slowly into the intestine, and (2) initiating the chemical processes of digestion. In order to understand the mechanism by which the stomach collects and then discharges the food, it is necessary first of all to recall certain anatomical facts concerning the organ, and for this purpose it is most convenient to accept the description given by Cannon, which is illustrated in Fig. 334. The organ is divided into a cardiac and a pyloric portion by a deep notch in the lesser curvature, called the incisura angularis. The cardiac portion is further subdivided into two by the cardiac orifice. The part which in man lies above a line drawn horizontally through the cardia is the fundus. The part lying between the fundus and the incisura angularis is known as the body of the stomach which, when full, has a tapering shape. The pyloric portion lying on the right of the incisura angularis is further divided into three parts: the pyloric vestibule, the antrum, and the pyloric canal, the last of which forms the lumen of the pyloric sphincter and in man measures about 3 cm. in length (see Fig. 334). From a study of the development and structure and from a consideration of its behavior when examined radiographically Cole[25] believes that the ascending or first part of the duodenum virtually belongs to the stomach and should be so considered when the gastric movements are under investigation. Since this portion of the duodenum receives and retains the chyme for a short time after its egress from the stomach and in radiographs appears to surmount the pyloric sphincter, he has termed it the "reservoir cap" or pilleus ventriculi.

The filled stomach of a person standing erect is so disposed that the greatest curvature forms its lowest point, which may be considerably below the umbilicus. As digestion proceeds and the stomach empties, the greater curvature becomes gradually raised, so that ultimately the pylorus comes to be the most dependent part of the stomach. From these and many other observations it is certain that the emptying of the stomach does not at all depend on the operation of the force of gravity. Indeed, that this cannot be the case is perfectly clear when we consider the disposition of the stomach in quadrupeds.

Exact observations on the movements which the stomach performs from the time it is filled with food until it empties, have been made by the x-ray method, first introduced by Cannon.[18] The method consists in feeding the animal with food that has been impregnated with insoluble salts of bismuth or barium, then exposing it to the x-ray and either taking instantaneous photographs of the shadows or observing them by means of a fluorescent screen. In the accompanying figure (Fig. 335) the outline of the shadow cast by the cat's

stomach is shown for intervals of an hour each during digestion. Soon after the stomach has become filled, peristaltic waves are seen to take their origin about the middle of the body of the viscus, and to course toward the pylorus. The region above the origin of these waves—that is, the cardiac half of the body of the stomach and all the fundus, often called the cardiac pouch—is free from peristaltic waves but is the seat of a tonic contraction which, as digestion proceeds,

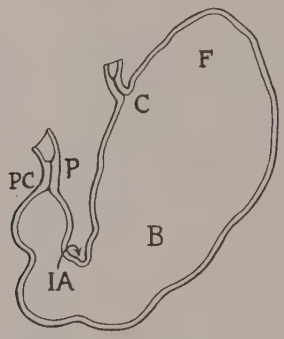

Fig. 334.—Schematic outline of the stomach. At *C* is the cardia; *F*, fundus; *IA*, incisura angularis; *B*, body; *PC*, pyloric canal; *P*, pylorus. The antrum is the portion from *IA* to *PC* inclusive. (From Cannon.)

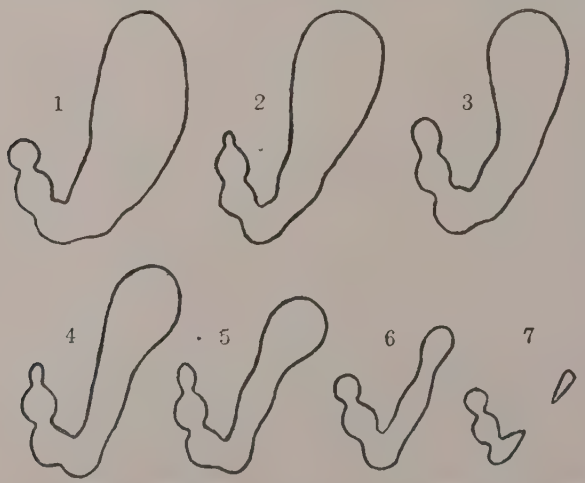

Fig. 335.—Outlines of the shadows cast by the stomach at intervals of an hour each after feeding a cat with food impregnated with bismuth subnitrate. (From Cannon.)

presses steadily with increasing force upon the mass of food and delivers it slowly to the lower and more active portion of the stomach.

As the food passes into the lower part of the stomach, the cardiac pouch becomes gradually reduced in size until finally, when the stomach is empty, its outline, as revealed by radiographs, departs from the pyriform shape characteristic of the full organ to assume a more or less tubular form.

From this description, it is evident that the function of the cardiac portion of the stomach is to serve as a reservoir for the food which by a slow contraction of the gastric wall is gradually delivered into the lower and more motile part of the stomach. The motor phenomena of this portion are of a complex nature and will now be considered.

Cole,[25] by the employment of serial x-ray photographs taken at short intervals has shown that this portion of the human stomach undergoes a succession of rapid changes in shape (Fig. 336), due to the peristaltic waves which course over it toward the pyloric sphincter. The pyloric region also exhibits alternate phases of increased and diminished tone while the waves are passing over it. The period of gastric activity intervening between a phase of complete relaxation and the reappearance of this phase is termed a gastric cycle. In some types of

Fig. 336.—Drawings made from skiagrams of the human stomach taken at intervals after food. A gastric cycle is illustrated. (After Cole.[24])

gastric motility a peristaltic wave takes but one gastric cycle to complete its journey from its origin to the pylorus. Such a wave would show in consequence one phase of complete relaxation and maximal contraction. In other types two, three or four gastric cycles may occur during the passage of the wave. The waves are therefore spoken of as one, two, three or four cycle types of peristalsis, respectively. It follows from this that at any moment the stomach will show one, two, three or four waves according to the particular type of peristalsis which is present. Cole considered four cycle to be the most common type whereas Alvarez reports that the three cycle is the most frequent; the rapid one cycle type is very rare.

The passage of a gastric cycle is from 2 to 3 seconds. The time required for the passage of a four cycle type of peristaltic wave from its origin to the pyloric

sphincter therefore will be from 8 to 12 seconds. It rarely exceeds 10 seconds. Following the cardiac analogy Cole divides the gastric cycle into a systole and a diastole. In the former, which occupies 7/10 of the cycle, the constrictions produced by the peristaltic waves are most marked. Diastole occupies 3/10 of the cycle and represents the period during which relaxation is taking place (Fig. 336).

The adaptation of the capacity of the normal stomach to the volume of its contents is remarkable. When the stomach of a living animal is distended by fluid, the intragastric pressure shows very little change even up to the point of rupture of the viscus (Grey[55]). After excision, the stomach loses in considerable measure this adaptive power.

The nervous control of the stomach movements is not entirely understood. An excellent idea of the complexity of these movements and the relatively enormous literature concerning them can be gained from a study of Chapter XV of Alvarez's monograph. There is considerable automaticity of the organ presumably dependent upon the rich nerve plexuses in its walls. Thus, coordination between the increasing tone of the fundus and the rhythmic contractions of the pylorus is probably dependent on Auerbach's plexus. More local movements, on the other hand, such as the advancing waves of the antrum, may be purely myogenic since they persist after the continuity of Auerbach's plexus has been destroyed, by making several circular cuts through the muscular coats of the stomach wall (Cannon). Of the extrinsic nerves the vagus seems to have a greater influence than the sympathetic, but the results which follow its stimulation vary considerably. They are unpredictable so far as the pylorus is concerned, and in the fundus they seem to depend very largely on the state of tone of the stomach at the time of stimulation (McSwiney and Wadge[88]), contraction occurring when this is low and relaxation when it is high. Stimulation of the vagus also causes the esophagus to contract. Stimulation of the sympathetic (splanchnic) usually causes diminution of tone and depresses the movements of the stomach.

Section of the vagi at a midthoracic level has been found to result in temporary paralysis of the lower portion of the esophagus where smooth muscle is present; if food is swallowed it distends the tube and the atonic walls fail to respond by contraction. A similar condition develops in the stomach; muscular tone is lost and there is an absence or marked depression of peristaltic activity. If food is introduced through a stomach tube, it may lie for hours undisturbed by any gastric motility. Later tone and motor activity reappear in the lower esophagus and swallowed food is passed into the stomach by peristaltic contractions. Gradually the tone and motility of the stomach walls return and after a few days the presence of food excites gastric peristalsis of normal type and vigor. The recovery of peristaltic activity seems dependent on the development of a state of intrinsic tone of the smooth muscle itself. Cannon made the important observation that severance of the vagi after food was taken does not seriously interfere with the digestion of that particular meal. He suggested that the stomach can exhibit a "psychic" increase in muscular tone which is a consequence of vagal excitation brought about by the pleasant taste of food. Both Cannon and Alvarez have likened this tonal phenomenon to the so-called psychic secretion of gastric juice which has been proved to require for its occurrence an intact vagus nerve supply. Alvarez has presented considerable clinical evidence that the pleasurable taking of food or even the anticipation of this experience may increase the tone and the motor activities of the entire gastrointestinal tract.

The evidence from experimental sectioning of the vagi indicates that an important function of these nerves is to set the smooth muscles of the lower esophagus and stomach in a state of continuous moderate contraction or tone upon which are superimposed the essential peristaltic contractions. These activities, however, can develop independently of the vagi

after their section. It is important to realize that the vagi are compound nerves and that there is evidence that all vagal fibers to the gastric musculature do not exert identical effects. For example Cannon and Lieb observed that whenever a swallowing movement occurs, the intragastric pressure drops. This "receptive relaxation" of the stomach, as they appropriately designated the phenomenon, denotes the presence of an automatic mechanism which lowers intragastric pressure while the esophagus is pushing new material through the cardia. Cannon states that this "reciprocal adjustment between the esophageal muscle and the gastric muscle wholly disappears after the vagus nerves have been severed." It follows that certain vagal fibers exert an inhibitory influence upon the gastric musculature.

It has already been stated that stimulation of the sympathetic supply to the stomach exerts an inhibitory influence upon the gastric smooth muscle. It also produces vasoconstriction in this region. Evidence has been obtained that no serious digestive upset follows complete removal of the sympathetic ganglia and chains in cats, dogs or monkeys (see Chapter XI) and it has long been known that bilateral splanchnic section does not appreciably affect gastric activities. Obviously the sympathetic supply does not contribute any essential factor to normal gastric motility or tone. It is, however, a factor in producing the inhibition of gastric secretion and motility which occurs as a result of painful stimulation or strong emotional excitement. This direct inhibition by nerve impulses is doubtless reinforced by the secretion from the adrenal medulla, which occurs under such conditions and which is itself a result of sympathetic activity (see Chapter XI). Further, Cannon and Murphy have shown that the splanchnic nerves are responsible for the retardation in the emptying of the stomach which occurs as a result of laparotomy and surgical handling of the stomach and intestines.

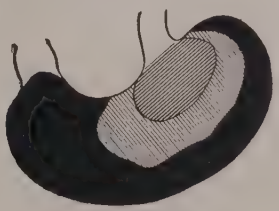

Fig. 337.—Diagram of a section through the frozen stomach (rat) some time after feeding three differently colored portions of food. (From Howell's Physiology.)

The Effect of the Stomach Movements on the Food.—This has been studied: (1) by dividing the food into portions that are differently colored and, after some time, killing the animal, freezing the stomach and making sections of it (see Fig. 337); (2) by making little pellets of bismuth subnitrate with starch and observing their behavior under the x-rays; or (3) by removing samples of the stomach contents by means of a stomach tube (Rehfuss tube) inserted so that its free end lies in either the cardia or the pyloric region. By the first of the above methods it has been found that first mouthfuls of food lie along the greater curvature, where they form a layer over which the subsequently swallowed food accumulates, with the last portions next the cardia. The pepsin and hydrochloric acid of the cardiac end, therefore, act soonest on the first swallowed portion of a meal, and the more recently swallowed central masses are not affected by the secretions for some time, so that opportunity is given for the saliva mixed with the food to develop its digestive action.

As has been shown by removing the stomach contents with a tube at various periods after feeding with starchy food, considerable amylolysis may go on for some time. When separate samples are removed in this way from the cardiac and pyloric parts, it has been found that for up to half an hour the contents of both have about the same percentage of sugar, but that for some time after this

interval the cardiac contents contain considerably more sugar than the pyloris. Later the percentages of sugar again become equal, no doubt on account of diffusion. The diastatic action in the fundus is finally brought to an end when the contents become completely permeated by the hydrochloric acid. In this connection it is worthy of note that the addition of hydrochloric acid up to the point of neutrality greatly accelerates the rate of diastatic digestion. As the outer layers of food in the stomach become partly digested on account of the action of the pepsin and hydrochloric acid, the food is slowly pressed into the active right half of the stomach, where by the action of the peristaltic waves it is moved on to the pyloric vestibule.

By observing the x-ray shadow cast by two pellets of bismuth subnitrate it has been noted by Cannon that, as the peristaltic wave approaches a pellet, it causes it to move forward more rapidly for a short distance, but soon overtakes it and in doing so causes the pellet to move back a little towards the fundus. This backward movement is less than the forward movement, so that after the wave has passed, the position of the pellet is a little forward of that which it would have occupied had there been no wave. The behavior of the pellet and, therefore, of the stomach contents, is very much like that of a cork floating at the edge of the sea; as each wave approaches, it hurries the cork on a little, but after its passage the cork recedes again until the second wave carries it still a little farther forward. As the peristaltic wave approaches the pyloric vestibule and becomes more powerful, its effect on the pellets becomes more marked.

These observations made on cats and other laboratory animals also apply in the case of man. Removal of the contents of the cardiac and pyloric regions separately with a stomach tube after feeding with a test meal of which a part was colored with carmine or charcoal, has shown that none of the coloring material was present in the contents of the pyloric end up to twenty minutes or so after the food had been taken. It then appeared but at first only in traces. Another important distinction between the food in the two portions of the stomach relates to its consistency. In the pyloric end it is semifluid and homogeneous in character; in the cardiac end, on the other hand, it is a lumpy, rather incoherent mass.

The gastric movements must greatly *facilitate the digestive processes* in the stomach. In the cardiac part the undisturbed condition of the food will, as we have seen, facilitate the digestive action of ptyalin, whereas in the body of the stomach the peristaltic waves, besides moving the food onward, will tend to bring fresh portions of mucous membrane and food in contact, so that the latter becomes more thoroughly mixed with the pepsin and hydrochloric acid. In the pyloric part, where no hydrochloric acid is secreted, the contents, already sufficiently acid in reaction, become more thoroughly churned up with the local pepsin secretion, so that proteolytic action progresses very rapidly. Little, if any, absorption occurs in the stomach.

The observations of Carlson, Ginsburg[49] and others indicate that the usually accepted explanation of the pains of gastric and duodenal ulcers; namely, corrosion and irritation of exposed nerve endings in the gastric and duodenal mucosae by highly acid stomach contents, is not correct. The pains of ulcer may be present when the contents of the stomach are alkaline and they may be absent when so-called hyperacidity exists. According to these authors the pains are analogous in origin to those of hunger, and are the result of contractions of the

stomach and duodenum, the nerves of which are in a hyperexcitable state. Hyperacidity, then, will affect the pain of ulcer only insofar as it increases the motility of the stomach.

THE EMPTYING OF THE STOMACH

The Control of the Pyloric Sphincter.—Pavlov originally advanced, and Cannon elaborated by experiment, the view that the acidity of the chyme constitutes the chief factor in the control of the pyloric sphincter. According to this idea, acidity on the stomach side of the sphincter causes it to open, whereas acidity on the duodenal side causes it to close, the latter stimulus being prepotent, so that food cannot leave the stomach so long as any remains unneutralized in the duodenum. Teleologically, this theory is a most attractive one; but, as Cannon himself pointed out there are certain known facts of gastric evacuation which do not conform with it. Thus, it fails to account for the rapid passage of water and egg white into the duodenum, and it leaves unexplained the normal emptying time of the stomach in certain pathological states in which the secretion is suppressed or greatly reduced (achylia). Cannon interpreted these and certain other facts as indicating that there are still other factors controlling the emptying besides that of acidity. When considering the controversy concerning Cannon's theory, it is well to bear in mind that Cannon's tests were made with food of normal consistency, and that he himself indicated his appreciation of the rôle of possible factors other than acidity. It has been shown that in addition to chemical stimulation, mechanical stimulation by the food masses adjacent to the sphincter is of great importance. In a general way, one may say that the sphincter obeys the law of the intestine (page 944), so that mechanical stimulation on the antral side causes it to open, whereas stimulation on the duodenal side causes it to close. Since the antral stimulation will be set up by the passage of peristaltic waves, their arrival at the sphincter will coincide with its relaxation. But this mechanism is complicated by the fact that stimulation by food in the duodenum is prepotent in the sense that it operates to prevent evacuation in the face of an opening stimulation arising in the antrum. It is apparently the "cap" or "caput" of the duodenum that is most sensitive in this regard, for as long as food remains here—and x-ray examination shows that it commonly remains for some time—evacuation does not readily occur as the peristaltic waves arrive from the antrum. The mechanism is still further complicated by the occurrence of more or less independent rhythmic contractions in the caput.

As a working hypothesis dealing with mechanical factors we may consider that the emptying depends upon the relative pressures of the contents of the pyloric antrum and the caput of the duodenum. When a strong peristaltic wave passes over the antrum it tends to open the sphincter and to raise the pressure of its contents above that in the caput so that some of the contents pass through before the wave reaches the sphincter, which then closes. Toward the end of digestion the tone of the sphincter relaxes so that regurgitation of food from duodenum to stomach may occur. The foregoing hypothesis, however, does not completely explain all of the observed facts; and, although space will not allow a complete review of the experiments relating to this problem, it may be useful to refer briefly to some of them.

From the study of serial radiographs in man Cole[25] observed that a definite relationship exists between the movements of the antrum and those of the pyloric

sphincter. The activities of the sphincter were found to be directly proportional to the magnitude of the antral contractions, and chyme passed into the duodenum during each of these but not in the intervals. Luckhardt, Phillips and Carlson[79] combining fluoroscopic observations with graphic records, obtained by means of a balloon inserted in the stomach, have also shown that the passage of chyme into the duodenum coincides with peristaltic waves traveling over the stomach. By observing the gastric contents collected from a duodenostomy opening made immediately below the pyloric sphincter it was noted that water placed in the stomach passed through the sphincter in gushes which was considered on the whole evidence of rhythm and it was assumed on this account that they were dependent upon peristaltic waves (Ivy). The water as it left the stomach was neutral in reaction. A more precise study of the interdependence of the antral and sphincter movements has been made by Wheelon and Thomas[122] who combined the study of radiographs with graphic records obtained by balloons placed in the antrum and pyloric canal. In this manner tracings could be taken of movements occurring simultaneously in the two regions. These observers found that when the peristaltic wave—commencing in the body of the stomach and

Fig. 338.—Tracings showing the relationship between contractions of the antrum (lower tracing) and the pyloric sphincter (upper tracing). Note that the antrum precedes the sphincter but that the latter contracts before the antrum has relaxed. (From Wheelon and Thomas.)

traveling over the vestibule—reaches the antrum the sphincter becomes relaxed so that any material swept forward by the constricting wave is free to pass through the pyloric opening. The wave is sufficiently broad to involve the whole antrum at one time and indeed it involves the sphincter before it has begun to disappear from the antrum with the result that for a short period the antrum and sphincter together are in the contracted state. Soon after this, the antrum enters upon its negative phase (relaxation) the sphincter being still contracted. These facts are shown in Fig. 338.

The foregoing studies are open to the criticism that the animals were anesthetized. The more recent observations of Thomas and associates[114, 115] were made in dogs provided with fistulae suitable for the insertion of the various balloons. In these experiments it was clearly demonstrated that as the gastric peristaltic wave approaches the pylorus there is, regularly, marked inhibition of the rhythmic contractions of the first 15 or 20 cm. of the duodenum. Recovery of activity in the duodenum begins at the same time as the contraction

of the pyloric sphincter that follows each gastric wave. The changes just described start at the pylorus and travel downward at a speed characteristic of the spread of descending inhibition (10 cm. per sec.) but more rapidly than ordinary peristalsis. In general, the gastric influence appears to be that of diminishing the activity of the part of the duodenum affected as compared to the activity of other unaffected parts. While food is being taken, it was observed that the contractions of the duodenum are inhibited along with those of the stomach. This work confirms that reported in 1910 by Joseph and Meltzer, who interpreted their findings as meaning that there is a receptive relaxation of the duodenum associated with each gastric peristaltic wave.

The recent studies of Meschan and Quigley[92, 103] are interesting in this connection. These workers used three tandem balloons located in the pyloric antrum, the pyloric sphincter, and the duodenal bulb in trained unanesthetized dogs, and showed that these three regions function together as a unit. Waves originating in the stomach were observed to pass successively over all three structures. Contrary to the generally accepted belief, the pyloric sphincter in these studies appeared to be passively relaxed most of the time, contracting only when a peristaltic wave reached it, this contraction being maintained while the wave continued over the duodenal bulb. It is obvious that such a contraction of the sphincter would operate to hinder regurgitation more than it does emptying. Vagotomy did not alter in any fundamental way this coordinated complicated relationship of antrum, sphincter, and duodenal bulb. The fact that the inhibitory effects on emptying of various substances placed in the intestine were greatly decreased or abolished by vagotomy indicates that these substances exert their influence through the enterogastric reflex. Thomas[113] has attacked this problem by measuring the pressures on the two sides of the pylorus in dogs provided with suitable fistulas. He observed cyclic changes in pressures associated presumably with the passage of a peristaltic wave; a complete cycle was most often observed when the stomach contained food; an incomplete cycle, characterized by lack of the initial rise of intragastric pressure, was most commonly seen when water was being evacuated. According to Crider and Thomas,[30] the acidity of the chyme in the intestine proves to be less important than the digestion products which may be present; proteoses accounted for about one-half of the inhibitory effect noted, peptones and other substances being responsible for the remainder.

It appears evident that the underlying mechanism controlling the emptying of the stomach is in some way related to the nervous one involved in the peristaltic contractions of the stomach. There is a suggestion that the movements of the antrum and pyloric sphincter follow the "law of the intestine" (page 944), perhaps with certain minor modifications. That some other factor also influences the emptying time is, however, certain. It is difficult, otherwise to account for the rapid passage from the stomach of water and egg white and the retention of other substances until they reach a more or less fluid consistency. It is likely that one important function of the stomach is to protect the duodenum as much as possible from hard discrete objects. A nervous mechanism with receptors in the antral wall responsive to unusual pressure stimulation of discrete small areas, such as would result from contact with hard objects contained in a large soft mass, might subserve this function. If the entire mass were soft, semifluid, with no hard particles in it, then contraction of the antrum should result in an equal distribution of the pressure through the operation of Pascal's principle.

Under such conditions, the mass in the antrum would be ready for discharge through the pylorus. Whether it would be so discharged could then depend upon the presence in the duodenum of the material discharged previously, as researches already suggest that this is a factor. If the mass has not been softened sufficiently, the above-described mechanism would operate to delay its discharge.

When there is food in the lower ileum and also in the stomach, the latter makes little effort to empty until the ileum has discharged its contents into the cecum. This is called the *ileogastric reflex*. When the vagus nerves are cut below the cardiac branches, much of the food remains for a long time in the stomach and is only slowly digested since the secretion of gastric juice is interfered with.

There is usually a considerable amount of *gas* in the part of the stomach above the entrance of the cardia, on account of which this part of the stomach has sometimes been called the stomach bladder. In the upright position this gas forms a bright area in the x-ray plate, but when the person reclines the gas spreads to a new location. Its presence may influence gastric digestion by preventing the contact of the food with the mucous membrane, and by interfering with the efficiency of the peristaltic waves in moving the food. Considerable gas therefore retards the emptying of the stomach, as has been shown experimentally by x-ray observations on animals in which feeding with the standard amount of food was followed by the introduction of air. It was noted that the air did not diminish the frequency or strength of the peristaltic waves, but that these could not act efficiently on the food. When the presence of gas is associated with atony of the stomach walls, the retardation in the discharge will, of course, be still more pronounced. The temperature of the swallowed food does not appear to have much influence on the stomach movements or on the rate of discharge from the organ.

Influence of Pathological Conditions on the Emptying of the Stomach.—An important surgical application of these facts concerns the *behavior of food after gastroenterostomy*. It has been thought that this operation would cause the food to be drained from the stomach into the intestine and thus leave the region of the stomach between the fistula and the pylorus inactive. This assumption is based on the idea, which we have seen to be erroneous, that gravity assists in the emptying of the stomach. As a matter of fact, if the gastroenterostomy is made when there is no obstruction at the pylorus, it has been found that the chyme takes its normal passage through the sphincter and, almost without exception, none leaves by the fistula. When the pylorus is partly occluded, the food sometimes passes in the usual way, and sometimes by the fistula. The cause for this predilection for the pyloric pathway depends on the pressure conditions in the gastric contents. Gastroenterostomy, therefore, is not likely to afford much relief except when gross mechanical obstruction exists at the pylorus.

Another objection to gastroenterostomy in the presence of a patulous pyloric sphincter rests on the fact that the food, after passing the sphincter and moving along the intestine, may again enter the stomach through the fistula. This is most likely to occur when the stomach is full of food, for under these conditions the stretching of its walls separates the edge of the opening, the intestine being drawn taut between the edges, so that the opening between the stomach and the intestine assumes the form of two narrow slits, which act like valves permitting the food to enter into but preventing its escape from the stomach. Only seldom under these circumstances can any food pass into the

intestine beyond the stomach opening. Repeated vomiting after gastroenterostomy has been observed in experimental animals only when obstructive kinks or other demonstrable obstacles were present in the gut, the obstruction being located in that part of the intestine beyond its attachment to the stomach.

When the pyloric obstruction is complete, food must, of course, leave by the fistula, digestion by the pancreatic juice and bile being still carried on because of the fact that bile continues to be secreted and it acts as a stimulus to the production of secretin (see page 895). Further provision for adequate digestion of food in such cases is secured as some of the food after leaving the fistula passes back for a certain distance into the duodenum where, however, it soon excites peristaltic waves, which carry it forward again. This insures thorough mixing with the digestive juices. From their experimental experience Cannon and Blake[19] recommend that, when the fistula must be made, it should be as large as possible and near the pylorus, and that the stomach afterward should not be allowed to become filled with food. To avoid kinking of the gut, they also recommend that several centimeters of the intestine should be attached to the stomach distal to the anastomosis.

CHAPTER LXIV

MECHANICAL FACTORS OF DIGESTION (Cont'd)

THE MOVEMENTS OF THE INTESTINES

The length of the small intestine and the size of the cecum of the large intestine vary considerably in different animals. In the carnivora, such as the cat, the small intestine is relatively short; in the herbivora, relatively long. Thus, it is about three times the length of the body in the cat, and four to six times in the dog; in the goat and sheep, it may be nearly thirty times the length of the body. In the carnivora the cecum is either absent or rudimentary, whereas in those herbivora which do not have a divided stomach the cecum is very large and sacculated, as is also the colon. The reason for the great size in herbivora is that practically the whole of the digestion of cellulose takes place in this part of the gut. This digestion, as we shall see later, does not depend on any secretion poured forth by the animal itself, but upon the action of bacteria and certain enzymes (cytases) that are taken with the vegetable food.

MOVEMENTS OF THE SMALL INTESTINE

The movements of the small intestine have been studied (1) by the bismuth subnitrate and x-ray method, (2) by observing them after opening the abdomen of an animal submerged in a bath of physiologic saline at body temperature, (3) by observing the changes in pressure produced in a thin-walled rubber balloon inserted in the lumen of the gut and connected with a recording tambour, and (4) by excising portions of the intestine and keeping them alive in a bath of oxygenated saline solution at body temperature.

The Segmenting Movements.—When a suitably fed animal is placed on the holder for examination by the x-ray method, no movement in the intestinal shadows is generally observed for some time. The first movement to appear is the breaking of one of the columns of food into small segments of nearly equal size. Each of these segments again quickly divides, and the neighboring halves suddenly unite to form new segments, and so on, in a manner which will be made clear by consulting Fig. 339. This *rhythmic segmentation,* as Cannon has called it, continues without cessation for half an hour or longer, and the food shadow does not meanwhile seem to change its position in the abdomen to any extent. The splitting up of the segment and the coming together of the neighboring halves proceed as a rule with great rapidity; thus, if we count the number of different segments during a definite period, we may find the rate of division in the cat to be as high as 28 or 30 per minute. In man the divisions occur at a frequency of approximately 10 per minute, which corresponds to the frequency with which sounds can be heard when the abdomen is auscultated. In certain animals, such as the rabbit, segmenting movements have not been observed, but instead of them there occurs a rhythmic to-and-fro shifting of the masses of food along the lumen of the gut; this is rapidly repeated for many minutes.

When the intestines are floated out in a warm bath of saline solution, it is seen that the rhythmic segmentation is caused by narrow rings of contraction.

Under such conditions also it is often noted that the loops of intestine sway from side to side. The balloon method also reveals the presence of slight waves of contraction that pass rapidly along the gut, and follow each other at the rate of 12 to 13 per minute. Both of the muscular coats of the intestine are involved in these contractions, and it is believed that they are responsible not only for the pendular movements but also for the rhythmic segmentation observed by the x-ray method. According to this view these movements are constantly passing along the intestine and become exaggerated by the mechanical stimulus which is offered by the masses of food which they therefore cause to be divided into portions.

Several functions can be assigned to these movements. They cause intimate mixture of the food with the digestive juices, and by bringing ever new portions of food in contact with the mucosa, they encourage absorption. They also have an important massaging influence on the blood and lymph in the vessels of the intestinal walls. Indeed, the passage of lymph from the lacteals into the mesenteric lymphatics seems to depend very largely upon these movements.

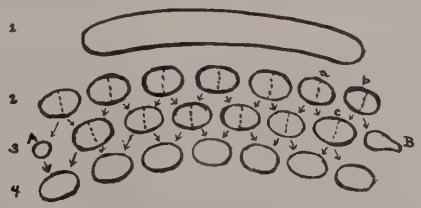

Fig. 339.—Diagrammatic representation of the process of segmentation in the intestine. An unbroken shadow is shown in *1* and its segmentation in *2*. The dotted lines across each mass show the position of division and in *3* is shown how new masses are formed by the split portions coming together. (From Cannon.)

The investigations of Alvarez[2, 3] and his co-workers show that the rhythmic intestinal contractions are not of uniform rate throughout the entire length of the small bowel, but vary in frequency inversely with the distance from the pylorus. For example, under the same experimental conditions the contractions of a duodenal segment proceed at a more rapid rate (17 to 21 per minute) than do those of an ileal segment (10 to 12 per minute). Associated with the variations in frequency are also differences in the amplitude of the contractions of the intestinal muscle. As the contractions become less frequent their amplitude increases. The tone and irritability of the intestine also diminish progressively from duodenum to ileum. According to Alvarez the underlying cause of the decline in contraction rate is to be found in a study of the metabolism of the intestinal muscle in the different regions. It was found that the respiratory metabolism (output of CO_2, use of O_2) of an excised strip, whether contracting or rendered quiescent by adrenalin, was greater the higher its origin in the small intestine. This direct relationship between the frequency of rhythm and the metabolic rate of intestinal muscle favors the view that the intestinal contractions are myogenic; this is supported by the further experimentally determined fact that the application of cocaine or nicotine does not abolish the contractions. Moreover, the graded activity of the muscle with regard to rhythm, tonus, and irritability is probably an important factor in the production of peristalsis and in the determination of the direction which this movement shall take.

The Peristaltic Movements.—The other movement observed in the small intestine is that known as the *peristaltic wave.* It occurs in two forms: (1) as a slowly advancing contraction (1 to 2 cm. per minute), preceded by an inhibition of the walls, and proceeding only through a short distance in a coil (4 to 5 cm.); and (2) as a swift movement called the *peristaltic rush,* which sweeps without pause for much longer distances along the canal.

Further analysis of the peristaltic wave can readily be made by the balloon method (Fig. 340). If the gut is pinched above the balloon, a marked relaxation occurs over the latter, and this relaxation extends for about two feet down the intestine. If, on the other hand, the gut is pinched a little below the balloon, a long-continued contraction occurs over the latter. The conclusion we may draw from this result is that the stimulation of the gut causes contraction above the point of stimulus and relaxation below, this being known as "the law of the intestine"—(Bayliss and Starling). We have seen that it applies also in the case of the cardiac and pyloric sphincters. In this connection it is of interest to report the observation by Alvarez[2] who was able to insert a balloon into an intestinal fistula in man; when the inflated balloon attached to a string was not allowed

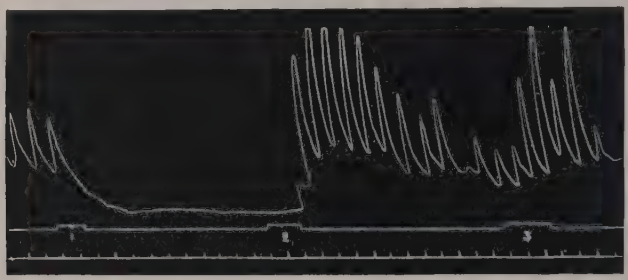

Fig. 340.—Intestinal contractions (balloon method) after excision of the abdominal ganglia and section of both vagi. Mechanical stimulation above (*1*) and below (*2*) the balloon causes relaxation and contraction respectively. (From Starling.)

to move with the peristaltic wave because the string was held taut, the patient soon experienced distress; evidently more vigorous contractions were produced in an endeavor to push the balloon forward and these were associated with symptoms of colic.

Carey[22] has made a study of the longitudinal and circular fibers of the wall of the small intestine and has found that they are arranged in a spiral manner; in excised loops a bolus was seen to move forward in a counterclockwise spiral path when viewed from the cephalic end. Reid, Ivy and Quigley[106] recently studied this matter in dogs provided with Thiry-Vella intestinal loops (loops both ends of which open through the body wall), and confirmed the report of Carey under a variety of physiological conditions. A similar conclusion was reached in studies where the x-ray method was employed. This rotational propulsion is apparently the same in the jejunum and ileum, and in these experiments was not altered by alimentation or by various drugs.

The Physiological Nature of the Rhythmic and Peristaltic Movements.—Much investigative effort has been expended in a study of the fundamental

mechanism involved in these intestinal movements. It has been found that the rhythmic segmentation type of movement is not affected by the application of cocaine or nicotine. Inasmuch as these drugs paralyze nervous structures it has been concluded that the rhythmic movements are myogenic in origin. The most recent work tends to confirm this opinion. Gunn and Underhill and later Alvarez and Mahoney recorded rhythmic contractions of small strips of the circular layer of intestinal muscle which were free from ganglion cells. Although it is possible that some nerve fibers from Auerbach's plexus remained in these preparations it seems most improbable that these disconnected axons supplied rhythmic stimuli to the smooth muscle cells. The peristaltic contractions, on the other hand, probably depend upon a local nervous structure, since they are paralyzed by the application to the gut of cocaine or nicotine. This local nervous system no doubt resides in Auerbach's plexus which must therefore be considered complex enough to direct nervous impulses so as to bring about a relaxation of the gut in front of the stimulus and contraction above it.

Nervous Control of the Movements.—The influence of the central nervous system on the intestinal movements has been studied by the usual methods of cutting and stimulating the extrinsic nerve supply. Through the splanchnic

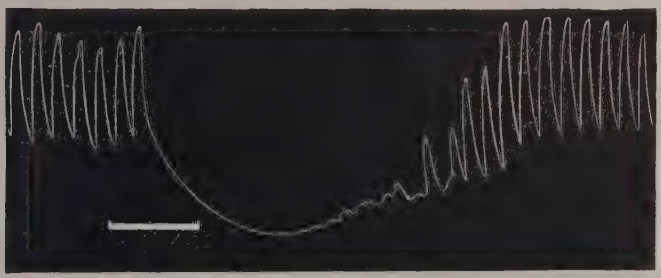

Fig. 341.—The effect of excitation of both splanchnic nerves on the intestinal contractions. (From Starling.)

nerves *inhibitory* impulses are conveyed to the intestine (except the ileocolic sphincter), so that after they have been severed the movements become more distinct. Indeed, in many animals after opening the abdomen no intestinal movement can be observed until the splanchnic nerves have been cut. Stimulation of the peripheral end of the nerve inhibits any movement which may be in progress (Fig. 341). The impulses through the vagus nerves are of an opposite character. Section of these nerves has little effect on the motility of the small intestine, but stimulation causes contraction (Fig. 342). Stimulation of a sensory surface even in an anesthetized animal will often inhibit the intestinal movements. After section of the splanchnics this inhibition does not occur.

By observing the rhythmic contractions of an isolated strip of the small intestine suspended in a bath of oxygenated saline solution at body temperature, it can readily be shown that the presence of even a minute trace of epinephrine is sufficient to produce complete inhibition of the movement. The parallellism between the effects of splanchnic stimulation and those of epinephrine is very significant, for it may be that the marked inhibition of intestinal movement which

occurs during fright and anger is the result of an increased secretion of this hormone from the adrenal glands (see page 171).

The circular muscular coat of the last two or three centimeters of the ileum before it joins the cecum is definitely thicker than the rest of this coat, indicating that it has a sphincter-like action. This *ileocolic sphincter,* as it is called, opens when food is pressed against it from the ileum, but remains closed when food is pressed against it from the cecum. It therefore obeys the law of the intestine. That it is physiologically distinct from the musculature of the rest of the ileum is indicated by the fact that the splanchnic and vagus nerves do not affect it in the same way; thus, stimulation of the splanchnic causes a strong contraction of the sphincter, whereas stimulation of the vagus has no effect.

Peristalsis is much more rapid in the duodenum than in other parts of the small intestine. During the first stages of digestion, the food ordinarily lies

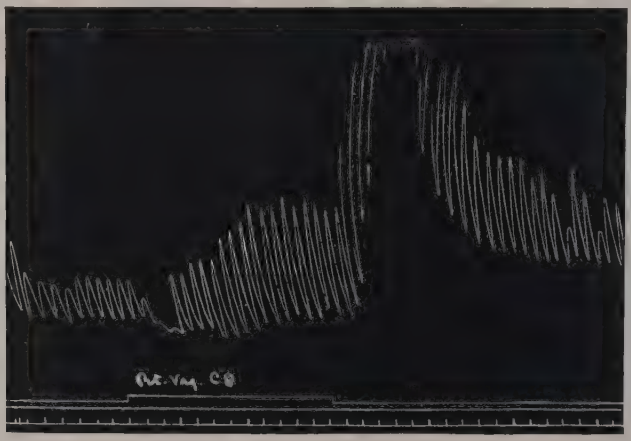

Fig. 342.—The effect of stimulation of right vagus nerve on the intestinal contractions. (From Starling.)

mainly in the right half of the abdomen, and later in the left half. There is considerable variation in the time that elapses before it enters the colon. In the cat, carbohydrates reach this part of the gut in about four hours.

The stimulation of the vagus nerves to the small intestine is probably associated with the production of a chemical agent which serves in the transmission of the nervous impulse, according to the recent work of Bunting[17] and associates. These investigators prepared denervated intestinal loops to be used as an indicator of the presence of acetylcholine or similar substances, and found that stimulation of the vagus was followed by contraction of the test loop. Evidently, therefore, the small intestine must be included in the structures provided with parasympathetic nerves which are cholinergic (see page 181).

Effect of Certain Clinical Conditions on the Movements.—Studies have been made of the effect of various surgical procedures on peristalsis and intestinal motility in general. The fact that peristalsis in the small intestine is in one direction, namely, toward the ileocolic valve, is readily demonstrated by separat-

ing a segment of the intestine, reversing it, and then suturing to restore continuity of the gut. If the reversed segment is less than about three inches long, little difficulty is experienced in the passage of material through it; if the segment is longer, its peristalsis now directed toward the stomach may be powerful enough to produce all the symptoms of intestinal obstruction.

After an *end-to-end anastomosis* of the gut, no evidence can be obtained by the x-ray method that any hesitation occurs in the movement of the shadows at the anastomosis. On the other hand, when a lateral anastomosis is established, stagnation of the food in the region of the junction may occur. The end of the proximal loop beyond the opening is also in danger of becoming filled with hardened material. Another objection to lateral anastomosis depends on the fact that in performing the operation a considerable amount of the circular muscle is cut, which interferes with peristaltic activity.

Observations have also been made by the x-ray method on the behavior of the intestinal contents following *intestinal obstruction.* It has been observed that as material collects in the gut just above the obstruction, strong peristaltic waves are set up, which move the food toward the obstruction so powerfully as to cause the walls of the canal in front to become bulged, until at last the pressure causes the contents to be squirted back through the advancing ring of peristaltic contraction. These waves succeed one another rapidly.

The type of peristalsis known as the peristaltic rush can be induced experimentally in animals by intravenous injection of ergot. It probably also occurs in conditions of abnormal irritation of the gut in man, and is believed to be the characteristic activity of the gut after administration of a strong purge.

MOVEMENTS OF THE LARGE INTESTINE

In considering the movements of the large intestine in man and their nerve control, it is necessary, as insisted on by Garry, to realize that observations made on laboratory animals may give but uncertain guidance, owing to the marked differences in the relative development of its various parts in different animals. In herbivores the proximal colon and cecum are large and sacculated; in carnivores they are small and simple tubes, and in omnivores the structure is intermediate between these two. The colon of man is sacculated in its ascending, transverse, and descending limbs, approximating the herbivorous rather than the carnivorous type, and the longitudinal muscular coat does not become continuous until the caudal part of the pelvic colon is reached. The pelvirectal flexure has a sphincterlike action, absent in the gut of laboratory animals, although in the dog there is constriction about 5 cm. craniad to the anus, above which the walls have a high degree of tone and below it are lax. The ileocolic junction has a true sphincter (Fig. 343).

It is impossible at present to give a clear description of the innervation of the lower bowel. Two factors are clear, viz., that the intrinsic nerve plexuses run parallel in their development with that of the muscular layers and that there is no sharp distinction of function between so-called sympathetic and parasympathetic fibers. Indeed, the effects of section or stimulation of a given nerve structure may give unlike results in different animals, even of the same species. The innervation for cat and man as far as is known is outlined in the accompany-

ing diagram (Fig. 344), but details concerning the exact functions of the various nerves in man must await the observations of surgeons in the operating theatre. (For a further description of these nerves and the literature, see the review by Garry.)

Quite apart from the dissimilarity in the anatomical arrangement of the nerves, it is most difficult to obtain consistent indications of their functions because these are affected by numerous influences, such as anesthesia, opening of the abdomen, and the degree of distention of the gut with food. The decerebrate animal is probably the most satisfactory preparation to use, but even this is open to objection because influences transmitted from suprabulbar regions are missing.

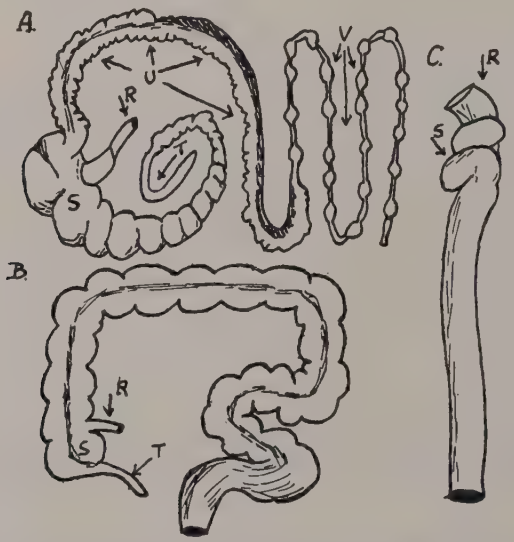

Fig. 343.—The large bowel. *A*. In the rabbit: *R*, ileum; *S*, cæcum; *T*, appendix; *U*, proximal colon; *V*, distal colon. *B*. In man: *R*, ileum; *S*, cecum; *T*, appendix. *C*. In the dog; *R*, ileum; *S*, cecum. (After Garry.)

Experimental investigation of the nature of the nerve control is best obtained by observing the effects of section; electrical stimulation of nerve trunks is of little value because it differs so widely from the normal and may involve simultaneous excitation of fibers exercising opposed effects, but mechanical stimulation, by distending a suitable balloon placed in the gut, gives useful information, and its effects and those of other procedures can be recorded by connecting the balloon with a tambour.

Opinions conflict with regard to the degree of autonomy of the large bowel. The proximal portions undoubtedly possess this to a much greater degree than the distal, the movements of the latter being normally dependent on the extrinsic nerve supply and disappearing after destruction of the lumbosacral regions of the cord. After a time which varies greatly in different animals, movements may return after decentralization, and defecation may occur at regular

intervals, but of course without any voluntary control. There is no evidence for supposing that there are extraspinal centers for the act of defecation.

The tone of the internal anal sphincter, composed of unstriped muscle, is maintained by fibers from the inferior mesenteric ganglia; after their section the whole anal canal dilates. The external sphincter is composed of a peculiar form of striped muscle—small fibers rich in sarcoplasm—and the relaxation which follows when its nerves are cut or the cord is destroyed disappears afterward, which has led some to believe that it can be controlled by local nerve ganglia. For striped muscle the external sphincter is peculiarly resistant to curare. There

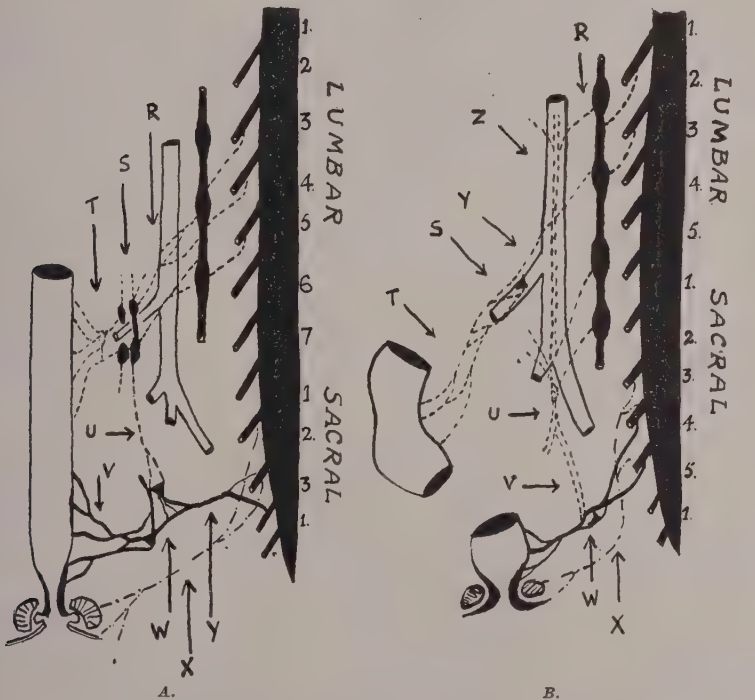

Fig. 344.—Nervous outflow to the distal colon (*A*) in the cat, and (*B*) in man.

A: R, spinal rami to inferior mesenteric ganglia; *S,* inferior mesenteric ganglia; *T,* lumbar colonic nerves; *U,* hypogastric nerve; *V,* sacral colonic nerves; *W,* pelvic plexus; *X,* pudendal nerve; *Y,* pelvic nerve.

B: R, pelvic splanchnic nerves; *S,* inferior mesenteric plexus; *T,* inferior mesenteric nerves; *U,* presacral nerve; *V,* hypogastric nerve; *W,* hypogastric plexus; *X,* pudendal nerve; *Y,* intermesenteric nerve; *Z,* intermesenteric plexus. (After Garry.)

is a defecation center in the lumbosacral region of the spinal cord and its activities are under the control of a higher center in the medulla. After spinal section between these two centers in man, defecation is paralyzed until spinal shock (page 88) has passed off when it returns as a purely reflex act. Section of the lumbar outflow of nerves leads to increased activity of the colon, as also does spinal anesthesia. These nerves seem to control the postural tone of the

bowel (Learmonth and Markowitz). Their section also causes relaxation of the internal anal sphincter. The sacral nerves have a motor influence and their section is followed by loss of tone of the colon. They also convey afferent impulses.

The importance of a knowledge of the functions of the various nerves is unquestioned from the surgical standpoint since most satisfactory results are often obtained by cutting them in Hirschsprung's disease (inhibition of the colon and contraction of the internal anal sphincter occurring in infants). It is possible that increased knowledge may point the way as to which nerves should be cut in certain cases of intractable constipation.

Apparently the movements are much the same in the cat as in man. As the food passes through the ileocolic sphincter into the cecum and accumulates there, it gradually sets up, by its pressure, a contraction of the muscular walls of the gut somewhere about the junction between the ascending and transverse colon. This wave of contraction then begins to travel slowly toward the cecum without, however, being preceded by any relaxation of the wall of the gut, as is the case with a true peristaltic wave. This first wave is soon followed by others, with the result that the food is kept in the cecum, being meanwhile prevented from passing into the ileum by the operation of the ileocolic sphincter and by the oblique manner in which the ileum opens into the cecum. These waves continue for three minutes or so; then the colon becomes passive and more material enters it from the ileum. These antiperistaltic waves, however, are not usual in man, but frequent small contractions may be seen in the cecum and ascending colon. The effect of the movements is to knead and mix the intestinal contents, and thus encourage the absorption of water from them.

In man also a massive peristaltic wave occurs three or four times a day driving the contents from the proximal into the distal portion of the colon, and the fecal matter collects proximally to the pelvirectal flexure. Some of it passes into the rectum as a result of one of the large peristaltic waves, and as a consequence the defecation reflexes are set up. The descending colon itself is never distended with contents and merely serves as a tube for transferring the masses from the proximal to the distal colon.

THE PELVIC COLON

By the time the distal colon is reached (6 to 8 hours after leaving the stomach), the intestinal contents have become definitely fecal in character; and they consist of indigestible matter (cellulose, etc.), bacteria, which are largely dead, the products of bacterial action, and some of the constituents of the bile. Two types of peristaltic waves have been observed in the distal colon: a slow movement, and what Holzknecht calls "large colonic movements" which serve to carry in a few seconds the intestinal contents through the greater part of the large intestine. The latter are analogous to the peristaltic rush movements of the small intestine. The "large" movement has been observed in man, particularly after a meal and, when related to the taking of a meal has been spoken of as the "gastrocolic reflex," which is most evident after the first meal of the day. If defecation is performed shortly after the urge due to this reflex is evident, the eliminatory act may usually be performed without undue effort. It is quite possible that these "large" movements also occur as part of the defecation act

itself, especially where this is accompanied by a subjective impression that emptying has been fairly complete. These movements are probably responsible for the discharge of soft or solid feces, which occurs at regular intervals one to three times a day, through fistulae placed distal to about the middle of the transverse colon.

DEFECATION—THE LAXATION PROBLEM

Defecation is partly a voluntary and partly an involuntary act. When material reaches the rectum, the pressure probably produces the desire to defecate. The involuntary part consists in large peristaltic movements in the descending and pelvic colon, which empty their contents into the rectum, and a relaxation of the two anal sphincters allowing the material to be evacuated. The voluntary act consists mainly in a contraction of the muscles of the abdominal wall; this contraction, together with forced inaction of the diaphragm by closure of the glottis, greatly increases the intra-abdominal pressure which aids in forcing the colonic contents into the rectum.

Mechanism of Defecation.—The underlying mechanism of defecation is undoubtedly an involuntary reflex. There is a center in the lumbosacral region of the spinal cord, and a higher center located in the medulla. As justification for the belief that an involuntary reflex is involved, one may cite Goltz's dog in which the entire spinal cord was removed except the cervical and upper thoracic segments. This animal, after recovering from the operation, defecated in normal fashion once or twice a day, indicating the existence of an intrinsic mechanism sufficient for consummating the act. The involuntary character of defecation in young infants is well known. The anal sphincters are normally in a state of vigorous contraction. It is difficult to state the extent to which this inhibition is entirely involuntary. The external sphincter, being composed of cross-striated muscle, is dependent for its tone on somatic nervous impulses and is under the control of the will. When the nerves are destroyed, the tone disappears and incontinence of feces results, but after some time the tone is reacquired independently of nervous impulses. The internal sphincter is composed of involuntary muscle supplied by autonomic nerves coming through the inferior mesenteric ganglia. The circumstances under which fecal incontinence so frequently occurs, particularly in aged people and in young untrained children, suggest that while inhibition normally occurs as part of the complicated reflex it is especially susceptible to cerebral influences, that is, to conditioning.

As material collects in the lower bowel, the tone of the musculature adapts itself to the volume of the contents, so that very considerable accumulation may occur. This adaptation to the size of the mass is readily demonstrated by balloon experiments. No doubt the pressure exerted by the material, in normal people at least, eventually reaches a threshold value and then acts as a stimulus for defecation. The observations of Cowgill and associates[27] suggest that there is a certain capacity of the lower bowel for expansion which accounts for the varying size of the stool; if the amount of material to be eliminated is greater than can be taken care of by this capacity for expansion, then more stools will have to be formed and passed in unit time, and therefore the rate of laxation will be increased.

It is a common belief that defecation at least once a day is a most desirable condition to maintain. It is interesting, therefore, to find Alvarez challenging this view: he points out that he has known many individuals who defecate once every two to four days, and who are apparently in no way harmed by such infrequent evacuation. Although this may be true, it is questionable whether this is sufficient justification for rejecting a more frequent defecation as the ideal to be attained by most people.

The Effects of Foods on Laxation.—Studies of this problem have shown that two types of influences may be exerted on laxation through the medium of foods: (1) one due to the bulk or mass upon which the colonic wall may contract, and (2) another due to the presence of substances which can stimulate the intestine directly by a species of drug action. The first may be illustrated by a comparison of the effects on the time of passage through the entire canal of two diets differing only in their content of indigestible material. If the differences in roughage content are sufficiently great the ration possessing the larger amount will pass through in shorter time and will be passed more easily in the defecatory act. The second type of influence is illustrated in the use of certain foods which seem to increase laxation out of all proportion to the amount of indigestible residue they contain. To what extent these two types of stimuli operate under ordinary conditions is difficult to say. The studies of Cowgill and coworkers[28] suggest, that in normal men at least, there is a definite relationship between rate of laxation and the intake of crude fiber. On the basis of their findings, these authors suggest that an intake of not less than 90 to 100 mg. of crude fiber per kilogram of body weight per day should be associated with satisfactory laxation determined not only by actual amount of material eliminated but by the subjective impressions of the individual as well. Working with a group of men, each of whom presented a history of chronic constipation, it was observed that these patients for some unexplained reason, showed a greater ability to decompose the ingested crude fiber of certain fruits and vegetables than did the normal men: a diet in which the crude fiber was furnished by fruits and vegetables and which gave satisfactory laxation in the normal men, did not do so with these patients; a change to a more resistant type of fiber such as that found in wheat bran, however, gave satisfactory results in both groups. In the one individual whose constipation was of the "irritable colon" type, no form of added roughage was tolerated; even agar-agar in large doses was objectionable, although a small daily dose proved fairly satisfactory. The more recent observations of Williams and Olmsted[126] and others[28, 56] suggest that these differences are probably due to the so-called crude fiber consisting of at least three substances, namely lignin, cellulose and hemicellulose, the presence of these carbohydrates in foods in varying amounts, and the fact that they differ in the extent to which they undergo bacterial decomposition during passage through the alimentary tract, lignin being most resistant and hemicellulose the least.

Ivy and associates[57] have made records of the contractions of the rectum in normal men and in patients suffering from constipation. The patients were found to be much less sensitive to increased pressure in the rectum than the normal individuals. This suggests that chronic constipation may be associated with a marked increase in the threshold for pressure stimulation in the rectum, with the result that the individual fails to respond in normal fashion to the presence of material in the distal colon and rectum ready for evacuation.

Sometimes the surgeon wishes to reduce the defecation rate to a minimum. If an operation is to be performed in the anal region, it is highly advantageous that defecation be delayed for many days, if possible, in order to promote healing and to avoid infection in the operated area. Clinical experience indicates the wisdom of feeding meat to such a patient. Hosoi, Alvarez and Mann[59] made a study of the amount of residue contained in the discharge from the small intestine following ingestion of various foods. Meat was found to have a low-residue value thus confirming the clinical impressions. Students searching for a low-residue diet will find the list of foods tested by Hosoi and associates full of valuable suggestions.

CHAPTER LXV

HUNGER AND APPETITE

The sensations of hunger and appetite are closely related in the sense that both are agencies which promote the taking of food. From the physiological point of view, however, they appear to be due to fundamentally different causes, and it is essential that the two be clearly distinguished. The sensation of hunger has been well described as "a dull ache or gnawing pain referred to the lower midchest region and the epigastrium" (Cannon), and it is definitely correlated with contraction of the stomach. Appetite, on the other hand, is a complex subjective experience compounded of a variety of psychic elements the most important of which are memory impressions of the sight, taste, and smell of palatable food. At present no evidence is available indicating that any specific bodily change underlies the sensation of appetite. Accordingly the following discussion will be concerned chiefly with hunger.

When in common parlance we say that we are "hungry" we usually mean only that we have a good appetite. Among prosperous people with regular habits there are individuals who experience the sensation of hunger only occasionally; in them appetite assures the taking of sufficient food. When, however, in a healthy person the ingestion of food is unduly delayed the more insistent demands of hunger are likely to lead to energetic activities directed toward the satisfaction of the bodily need. The fundamental differences between hunger and appetite have been aptly illustrated by Cannon in his discussion of this subject: "Hunger may be satisfied while the appetite still calls. Who is still hungry when the tempting dessert is served, and yet are there any who refuse it, on the plea that they no longer need it? On the other hand, appetite may be in abeyance while hunger is goading. What ravenous boy is critical of his food? Do we not all know that 'hunger is the best sauce'? Although the two sensations may thus exist separately, they nevertheless have the same function of leading to the intake of food, and they usually appear together. Indeed, the coöperation of hunger and appetite is probably the reason for their being so frequently confused."

HUNGER

In the main two opposed theories have been put forward to explain the sensation of hunger. The first and oldest of these is that hunger results from some general condition of the body, such as a lowering of the content of food substances in the blood. It has been supposed that the reduction in circulating nutritive material, or some change resulting from this, acts upon the brain to produce the sensation. No evidence, however, has been put forward to indicate that any change in the blood is a necessary condition for the development of hunger. As a matter of fact two of the most characteristic features of the sensation, its quick onset and its intermittency, alone suggest that some critical change in the body rather than the slow attainment of a low level of nutrition underlies the subjective experience. In the absence of positive evidence that hunger is a general sensation the older view has given place to the theory that hunger is the result of a specific gastric change.

The first direct proof that hunger is associated with contractions of the stomach was secured by Cannon and Washburn in 1911. The motor phenomena

which they studied were revealed by a technique which has been used in subsequent investigations of hunger (Fig. 345).

Cannon has described the general procedure used in the experiments. Mr. Washburn, at that time a medical student, first accustomed himself to the presence of a rubber tube in the esophagus. When a record was to be taken, a thin-walled rubber balloon fastened on the end of the tube was swallowed. The balloon was then moderately distended with air and connected with a suitable manometer and recording device. Contractions of the fundus of the stomach were thus registered in the usual way on a kymograph. "On the days of observation Washburn would abstain from breakfast, or eat sparingly; and without taking any luncheon would appear in the laboratory about two o'clock. The recording apparatus was arranged as above described. In order to avoid any error that might arise from artificial pressure on the balloon, a pneumograph, fastened below the ribs, was made to record the movements of the abdominal wall. Uniformity of these movements would show that no special contractions of the abdominal muscles were made. Between the records of gastric pressure and abdominal movement, time was marked in minutes, and an electromagnetic signal traced a line which could be altered by pressing a key. All these recording arrangements were out of Washburn's sight; he sat with one hand at the key, ready whenever the sensation of hunger was experienced to make the current which moved the signal." (Cannon.)

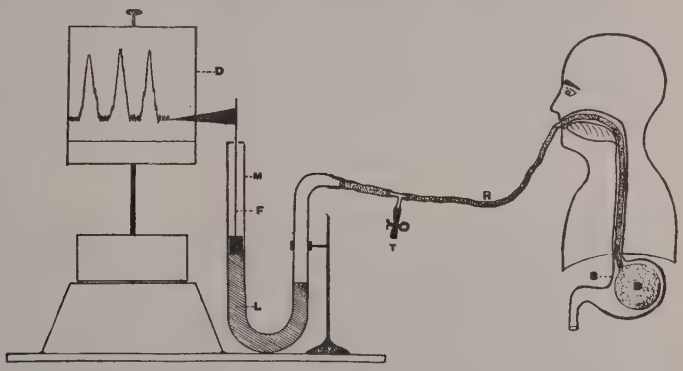

Fig. 345.—Diagram of method for recording stomach movements. *B*, rubber balloon in stomach; *D*, kymograph; *F*, cork float with recording flag; *M*, manometer; *L*, manometer fluid (bromoform, chloroform, or water); *R*, rubber tube connecting balloon with manometer; *S*, stomach; *T*, side tube for inflation of stomach balloon. (From Carlson.)

This relatively simple method at once showed that in man contractions of the stomach occur concomitantly with the pangs of hunger. When hunger was not experienced by the subject, there were no contractions of the empty stomach. Whenever the sensation was felt, powerful contractions of the stomach were recorded. Typically there were periodic recurrences of the sensation and each was associated with a marked rise in intragastric pressure (Fig. 346). It is significant that almost always the contraction was well advanced before the subject recorded the beginning of the sensation. This fact is evidence that the contraction precedes the sensation; indeed it strongly suggests that the contraction is actually the immediate cause of the sensation.

Shortly after this pioneer work the study of hunger was taken up by Carlson of Chicago who made observations on himself and his collaborators as well as on a man with a permanent gastric fistula. Carlson and his collaborators confirmed the evidence brought forward by Cannon and Washburn, and in a long series of studies they have greatly extended our knowledge of the

nature and control of hunger. Much of the material used in this chapter is taken from their published results. The monograph by Carlson should be consulted for further details.

The record obtained when the balloon is placed in the empty stomach of a normal person shows four types of waves. Two of these may be discounted, for they are due to the arterial pulse and the respiratory movements. The third is known as the *tonus rhythm*, and is caused by tonic contractions of the fundus which vary in amplitude (Fig. 347). These changes in tone are not necessarily accompanied by subjective sensations of hunger.

The fourth and most significant type consists of powerful *rhythmic contractions*, alternating with periods of quiescence. These contractions occupy a period of about thirty seconds, and are superimposed upon the tonus rhythm. They gradually increase in amplitude and frequency and, in the case of young and vigorous persons, may pass into a condition of incomplete tetanus, after

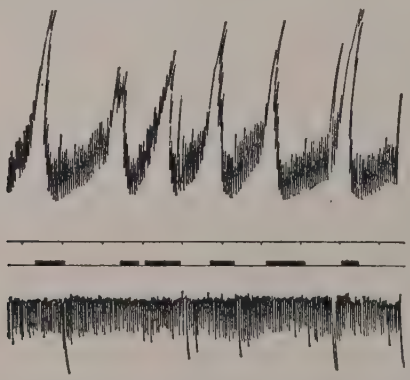

Fig. 346.—Copy of the first record of hunger contractions associated with hunger pangs, made May 17, 1911. First published by Cannon and Washburn, 1912. The top record represents intragastric pressure, the small oscillations being due to respiratory movements, the large to contractions of the stomach; the second record is time in minutes; the third record is Washburn's report of hunger pangs; the lowest record is respiration registered by means of a pneumograph about the abdomen. (From Cannon: Digestion and Health, New York, 1936. W. W. Norton and Company.)

which they suddenly subside, leaving only a faint tonus rhythm. The rhythmic contractions are definitely associated with the sensation of hunger, and are more marked the more intense the sensation is. When tetanus occurs the hunger sensation is continuous, but it instantly disappears when the tetanus gives place to relaxation.

When the contractions are comparatively feeble, the length of the period during which they occur is about twelve minutes. When the contractions are powerful, the periods are always initiated by weaker contractions with long intervening pauses; finally the pauses disappear and the contractions become more and more pronounced until, as mentioned above, a virtual tetanus lasting from two to five minutes, may supervene. The duration of the entire hunger period varies from one-half to one and a half hours, with an average of from thirty to forty-five minutes, and the number of individual contractions in a

period varies from twenty to seventy. Between the hunger periods, intervals of from one-half to two and one-half hours of quiescence may supervene.

Similar contractions, often passing into activity resembling incomplete tetanus in skeletal muscle, have been observed in the stomach of healthy *infants,* some of the observations having been made before the first nursing. The intervals of motor quiescence between the hunger periods are shorter than in adults. In observations made during sleep, it was observed that, when the contractions were very vigorous, the infant would show signs of restlessness and might awake and cry. As in the adult, the contractions are evidently associated

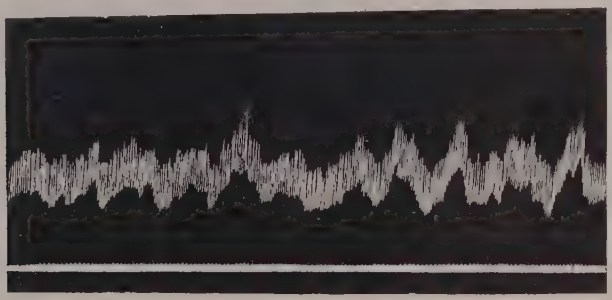

Fig. 347.—Tracing of the tonus rhythm of the stomach (man) three hours after a meal. (From Carlson.)

Fig. 348.—Tracings from the stomach during the culmination of a period of vigorous gastric hunger contractions. One-half original size. (From Carlson.)

with subjective sensations of hunger. Contractions of the empty stomach have also been recorded on a large variety of animals, including the dog, cat, rabbit, guinea pig, bird, frog, and turtle. They vary somewhat in type in different animals.

With regard to the time of onset of the tonus and hunger contractions it has been observed that the only period during which the fundus is free from them is immediately after a large meal. After a moderate meal the tonus rhythm begins to appear in about thirty minutes. It gradually increases in intensity, until by the time the stomach has nearly emptied itself the tonus has become conspicuous, and the stronger hunger contractions usually begin to ap-

pear. Superimposed upon those of the tonus rhythm, hunger pangs may appear in man *when the stomach still contains* traces of food.

By studying the shadow of the outline of the stomach produced by having a person or animal swallow two balloons, one inside the other and with a paste of bismuth subnitrate between them, it has been observed that the weaker type of hunger contraction begins as a constriction involving the cardiac end of the stomach, and moves toward the pyloric end as a rapid peristaltic wave. When the contractions are very vigorous, this wave spreads so rapidly over the stomach that it is difficult to determine whether it really occurs as a very rapid peristalsis or as a general contraction. At the height of the contraction the lower portion of the stomach may become so constricted that the cavity is completely obliterated. These contractions resemble very closely the movements that have sometimes been observed after a bismuth meal of the ordinary type and they have been thought by clinical observers to indicate a hyperperistalsis of the stomach. The digestion contractions of the filled stomach, therefore, pass gradually over into the hunger contractions of the empty organ.

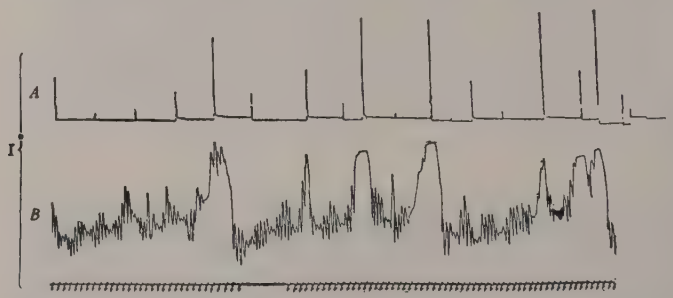

Fig. 349.—Showing augmentation of the knee jerk (upper tracing) during the marked hunger contractions (lower tracing). (From Carlson.)

Remote Effects of Hunger Contractions.—It is well known that during hunger certain general subjective symptoms are likely to be experienced, such as a feeling of weakness and a sense of emptiness, with a tendency to headache and sometimes even nausea in persons who are prone to headache as a result of toxemic conditions. Headache is likely to be more pronounced or perhaps present only in the morning before there is any food in the stomach. These symptoms indicate that hunger contractions are associated with hyperexcitability of the central nervous system, and it is of considerable interest that objective signs of this association can be elicited. If the knee jerk be recorded along with a record of the gastric contractions, it will be found that this reflex shows a marked exaggeration which is simultaneous with the strong hunger contractions of the empty stomach; this augmentation is greatest at the height of the stomach contractions, when the hunger pangs are most intense, and falls off again to normal when these disappear (Fig. 349). Further changes occurring during the hunger period include an increase in the pulse rate and vasodilatation. By comparing plethysmographic tracings of the arm volume with simultaneous records of stomach contractions, it has been found that the increase in volume occurs *pari passu* with the increasing tonus of the stomach, but that shrinking

of the arm begins before the stomach contraction has reached its maximum. Occasionally, however, as in acute hunger, a somewhat different relationship obtains, vasodilatation being more prominent. During each hunger contraction there is also increased salivation, the degree of which varies with different individuals. This response is independent of the more copious "watering of the mouth" that accompanies the thought and sight of appetizing food.

Hunger During Starvation.—During enforced starvation for long periods of time, it is known that healthy individuals at first experience intense sensations of hunger and appetite, which last, however, only for a few days, then become less pronounced and finally almost disappear. It is of interest to know the relationship between these sensations and the hunger contractions in the stomach. This has been investigated by Carlson and Luckhardt, who voluntarily subjected themselves to complete starvation, except for the taking of water, for four days. During a great part of this time records of the stomach contractions were taken by the balloon method, and it was found that the tonus of the stomach and also the frequency and intensity of the hunger contractions became progressively more pronounced as starvation proceeded. Towards the end of the period it was also noted that incomplete hunger tetanus made its appearance where ordinarily, as in Carlson's case, this type of hunger contraction was infrequent. Sensations of hunger were present more or less throughout the period, being therefore probably due to the persistently increased tonus. The onset of a period of hunger contraction could usually be foretold by an increase in the hunger sensation, and as these contractions became more marked, the hunger sensations became more intense. On the last day of starvation a burning sensation referred to the epigastrium was added to that of hunger. The appetite ran practically parallel with the sensation of hunger, and both of these sensations became perceptibly diminished on the fourth or last day of starvation, this diminution being, however, most marked in the sensation of appetite. Indeed, instead of an eagerness for food, there developed on the last day a distinct repugnance or indifference towards it. Accompanying these sensations of hunger and appetite a distinct mental depression and a feeling of weakness were experienced during the latter part of the starvation period.

On partaking of food again the hunger and appetite sensations very rapidly disappeared and also practically all of the mental depression and a great part of the weakness. Complete recovery from the latter, however, did not take place until the second or third day after breaking the fast. From this time on both men felt unusually well; indeed they state that their sense of well-being and clearness of mind and their sense of good health and vigor were as greatly improved as they would have been by a month's vacation in the mountains. They further point out that, since others who have starved for longer periods of time unanimously attest to the fact that, after the first few days, the sensations of hunger become less pronounced and finally almost disappear, they must have experienced the most distressing period during their four days of starvation. Although the hunger sensation was strong enough to cause some discomfort, it could by no means be called marked pain or suffering, and was at no time of sufficient intensity to interfere seriously with work. Mere starvation cannot therefore be designated as acute suffering. It is of further interest to note that during the starvation period a continuous flow of acid

gastric juice was found to be occurring in the stomach, to the presence of which the burning sensation experienced in the epigastrium on the last days is probably to be attributed.

Control of the Hunger Mechanism.—Carlson showed that hunger contractions of the empty stomach occur after complete isolation from the brain and spinal cord but at longer intervals and with less vigor than in normal animals. This suggests that chemical changes in the blood acting directly on the stomach may be responsible for them. It is of significance in this connection that when the blood sugar level is lowered by about 25 per cent, as by the use of insulin, hunger contractions become very marked, to disappear promptly when the lack of sugar in the blood is met by injection of the carbohydrate. The contractions are more vigorous when the innervation is intact. These experimental observations serve to explain the pronounced hunger sensations experienced by individuals who have received too much insulin.

Variations and Inhibitions of the Hunger Contractions.—The stimuli that may set up efferent impulses traveling by the extrinsic nerves to the stomach are impulses in sensory nerves or are of psychic origin. Stimulation of the gustatory end organs in the mouth, as by chewing palatable food, always causes an inhibition of gastric tonus and a diminution or disappearance of the hunger contractions. Even the chewing of indifferent substances, such as paraffin, suffices to produce distinct inhibition, unless the contraction has passed into a tetanus. It is of interest that swallowing movements, in the absence of any food substance in the mouth, are sufficient to produce a transitory inhibition of the gastric tonus—a receptive relaxation of the stomach, as it has been aptly called. The diminution in tonus and hunger contractions brought about in these various ways is accompanied by a diminution in the hunger pains.

Afferent nerve stimulation affecting the hunger contractions may also originate in the *gastric mucosa itself,* as was shown by Carlson when he introduced various substances to be tested through a tube into the stomach of his patient (Mr. V.). A glassful of cold water given in this way inhibits the tonus and the hunger contractions, unless these are severe, for from three to five minutes; this inhibition is not followed by any augmentation either of the tonus or of the contractions. Ice-cold water has a greater effect than water at body temperature.

Weak acids of strengths varying up to that found present in the gastric juice itself—0.5 per cent—cause a marked inhibition of the hunger movements, but this inhibition does not persist until all the acid has either escaped from the stomach or been neutralized, a fact which explains why hunger contractions may still occur when an acid secretion is present in the stomach, as in starvation. Normal gastric juice itself produces an inhibition, which is no doubt dependent upon the acid which it contains, but there is no basis for the view that, at the same time that it leads to inhibition of the hunger contractions, the acid initiates peristalsis of the pyloric region. Weak alkaline solutions have no greater effect on the hunger contractions than an equal volume of water. Weak solutions of local anesthetics, such as phenol or chloretone, are without effect.

With regard to *alcoholic beverages* interesting results were obtained. Wine, beer, brandy, and diluted pure alcohol inhibit both the tonus and the contractions. The duration of this inhibition varies directly with the quantity of the beverage introduced into the stomach and with its alcohol percentage. These

observations are apparently not in harmony with the experience of most men that the taking of alcoholic beverages serves to awaken or increase the appetite, the difference being no doubt due to the fact that hunger contractions of the stomach and appetite are not dependent on one another. As we have already seen, appetite is a complex psychic affair, whereas the hunger contractions and the sensations they arouse depend upon a local mechanism in the stomach wall itself.

The hunger contractions may be inhibited by the presence in the intestines of different substances, for example, carbohydrates, milk, oil, water, alkalies, and gastric juice. The mechanism by which this type of inhibition is brought about has been studied recently by Quigley and Phelps,[104] who placed carbohydrate in the intestines of dogs provided with a completely denervated isolated stomach or a completely denervated auto-transplanted gastric pouch. It was concluded that the inhibition of the motility of the empty pouches must involve a depressant humoral factor or chalone; a nervous factor may normally be involved because inhibition of the contractions of the normal stomach is produced by less carbohydrate, has a shorter latent period and lasts longer, but these differences may indicate merely a reduced susceptibility of the denervated tissue to the humoral factor. Action of this humoral factor depends on the presence of the carbohydrate in the upper intestine but not in the stomach itself.

Various other inhibitory factors have been discovered. Smoking has this effect, and compression of the abdomen by tightening the belt also inhibits the contractions, provided they are not of marked intensity. Considerable muscular exercise, such as brisk walking or running, causes an inhibition, which usually persists until the exercise is discontinued. When the tonus and the contractions return after exercise, they seem to be somewhat more pronounced. Application of cold to the surface of the body causes an inhibition of the gastric tonus and hunger contractions, the degree of which is roughly proportional to the intensity of the stimulation. If such stimulation is maintained, the inhibitory effects on the stomach gradually diminish, even though the individual be shivering intensely; there is never an increase in the gastric tonus and the hunger contractions.

With regard to *the nerve centers concerned in these phenomena,* little that is definite is known. The sensory nuclei of the vagus nerve in the medulla must be considered as the primary hunger center, and through this center, not only influences affecting the stomach contractions, but also those associated with the hunger sensations, must be mediated. It would appear from observations on the hunger behavior of decorticate animals that there can be no absolutely essential hunger center located in the cerebral cortex itself, for such animals exhibit practically the same hunger effects as normal animals. It is interesting to note that, at least in the case of "decorticate" pigeons, this hunger behavior entirely disappears on removal of the optic thalami. It appears therefore that important nerve centers having to do with the bodily responses of the animal to hunger impulses are located in the brain stem, presumably in the diencephalon.

Concerning the influence of psychic states, Carlson says that in his own case the hunger contractions became weaker and the interval between them greater when he was suddenly awakened during his fast and saw two of his friends partaking at his bedside of a "feast of porterhouse steak with onions, potatoes,

and a tomato salad." These results are no doubt due to local inhibition dependent upon the psychic secretion of appetite gastric juice. When no such juice is produced, the sight and smell of good food do not appear to affect materially the hunger contractions of the stomach. No doubt they stimulate the appetite, but that, as we have seen, is a psychic affair.

In the diagnosis of gastric and duodenal ulcer stress has been laid upon the occurrence, two to three hours after a meal, of pains which are relieved by the ingestion of food. The pains are probably due to hunger contractions. They can often be relieved by administration of alkalies of which the most useful for repeated use is a mixture of sodium bicarbonate, calcium carbonate, and magnesium carbonate. This has the advantage over sodium bicarbonate alone in that it causes less disturbance of the acid-base equilibrium of the organism. The alkali acts by neutralizing the excess of acid which is contained in the gastric secretion in cases of duodenal ulcer. Another type of treatment is to give olive oil. This acts by its inhibiting effect on gastric secretion (see page 911).

CHAPTER LXVI

THE BIOCHEMICAL PROCESSES OF DIGESTION

In a book on physiology, as distinct from a treatise on biochemistry, it would be out of place to enter into details concerning the chemical processes taking place during the digestive process. There is, however, a certain amount of fundamental knowledge which it is essential that we should consider. In the first place, it should be borne in mind that in the digestion of carbohydrates and proteins, various intermediate stages are passed through before the final absorption products are formed. The highly complex molecule of which protein, for example, is composed, is first of all broken down into several smaller but still highly complex molecules, each of which then undergoes further disruption, until ultimately the amino acids or relatively simple combinations of them are set free. Certain enzymes, such as trypsin, can carry this process from the beginning through the greater part of its course without the assistance of other enzymes, but in the natural process of digestion, as it occurs in the gastrointestinal tract, the different stages of the disruption are brought about successively by different enzymes. One enzyme prepares the food for the action of the next. This interdependence of their actions demands that some provision should be made whereby each enzyme is secreted at the proper time; that is, when the foodstuff has already been prepared for its action by that of its predecessor. Thus, it would be useless after food is taken for the gastric and pancreatic juices to be secreted at the same time. Instead, the gastric juice is secreted first and the pancreatic only after the food has been prepared for its action. This correlation in function we have already seen to be dependent largely on the action of hormones.

SALIVARY DIGESTION

The biochemical processes of digestion in man begin with the action of saliva. The most important constituents of the saliva are the amylolytic enzyme *ptyalin* and *mucus*. The amounts of these substances are subject to some variation. Some individuals, otherwise normal, show very little ptyalin in their saliva, in contrast to others whose saliva possesses considerable digestive power. Therefore one cannot consider a measurement of salivary activity as any index of serious abnormality. The saliva of certain species, the dog, for example, is devoid of ptyalin. The dog must rely on the amylase in his pancreatic juice to digest any swallowed starch, and this may be the reason why dogs exhibit increased laxation when forced to subsist on diets high in starch content. The saliva of the rat has great amylolytic power enabling this species to thrive on starch-rich rations. The mucus present in saliva plays an important rôle in lubricating the swallowed bolus.

In the saliva of healthy persons are also found traces of various nitrogenous metabolites—urea, uric acid, etc.—that occur in the blood. The amounts of these substances have been found to vary, the variations reflecting to a considerable degree the concentration changes in the blood. In nephritis, for example, when urea and other metabolites fail to be eliminated sufficiently through the

kidneys and therefore increase in the blood, they increase in the saliva. These facts suggest that chemical analysis of the saliva for these metabolites might perhaps be substituted for blood analyses in diagnostic work, but careful tests of this possibility have revealed that the blood analyses are much more significant. The fact that the saliva may contain relatively large amounts of nonprotein nitrogenous constituents of the blood is of practical clinical value in that the salivary glands may be made to function as one channel of excretion of such substances in case of kidney stress.

Oral administration of sodium iodide soon results in the passage of iodide from the blood into the saliva. This, together with the fact that iodide is not absorbed in the stomach and must therefore pass into the intestine before it can reach the blood, constitutes the physiological basis for the very simple iodide gastric-motor-function test. By timing the appearance of iodide in the saliva following the ingestion of a small capsule of the drug (0.2 Gm.), the time required for the passage of the iodide through the stomach is roughly determined. In cases of iodism considerable iodide is found in the saliva.

Factors influencing salivary digestion are: (1) the amount of ptyalin contained in the saliva, (2) the thoroughness with which the saliva is mixed with the food, and (3) the time during which the enzyme is allowed to act. The result of the action of ptyalin is to split digestible starch to yield the disaccharide maltose. The term "digestible starch" is used here because it has been shown that not all substances classified as starch by the organic chemist are acted upon by the various starch-splitting enzymes in the animal body. Cooked starch is much more readily digested than raw starch. The common idea that raw starch is absolutely indigestible has been shown to be erroneous; there seems to be some relation between the size of the starch granule and its susceptibility to amylase activity, the small granules being much more readily digested than the large granules. This may, perhaps, be due to the fact that the smaller granule has relatively much more surface to present to the enzyme than the large granule. Cooking in all probability acts to rupture the starch grains breaking the hemicellulose cell wall and thus facilitating the contact of the starch with the enzyme.

Reference has already been made to the belief of certain faddists that food should be chewed for long periods in order to "get the most nourishment out of it." There is little doubt that this extensive chewing would result in more complete digestion of the starchy portion of the food. As has already been pointed out, however (see page 921), salivary digestion can proceed for a considerable period in the stomach before the ptyalin is inactivated by the acid gastric juice, and this constitutes a serious argument against the position of these faddists.

Saliva is usually faintly alkaline in reaction. Variations from this have been believed by certain students to be related in some way to the problem of dental caries, particularly when combined with the action of acidophilic bacteria in the mouth. It has also been supposed that the drinking of acid wines and similar fluids at meal time may be detrimental to the action of ptyalin because the optimal reaction for the enzyme is very close to neutrality (pH 6.8). Actual experiment, however, indicates that the ability of common foods and drinks to impair salivary digestion beyond that to be expected by mere dilution of the saliva, may be questioned.

The maltose, which results from the action of ptyalin on starch, is split to yield glucose by the action of a maltase found in the intestinal juice, and the glucose is then absorbed through the intestinal wall.

DIGESTION IN THE STOMACH

The gastric juice contains several important digestive agents: (1) the enzyme pepsin, (2) hydrochloric acid which cooperates with pepsin in its digestive activity, (3) gastric rennin which clots milk, and (4) gastric lipase. The pepsin and the hydrochloric acid are undoubtedly the most important of these substances; they are found particularly in the juice secreted in the cardiac end of the stomach; toward the pyloric end the hydrochloric acid entirely disappears and the pepsin content becomes distinctly less.

The Functions of Hydrochloric Acid.—The functions of hydrochloric acid may be conveniently divided into physiological and biochemical. The former come into play after the chyme has entered the duodenum, and they have to do with the secretion of pancreatic juice and bile through the secretin mechanism (see page 895). The biochemical functions are: (1) assisting the pepsin in the digestion of proteins, (2) bringing about a certain degree of splitting of disaccharides, and (3) exerting an antiseptic action on the stomach contents. Regarding the last mentioned of these functions, it may be said that the chyme of a normal person, as it is ejected from the stomach, is practically but not absolutely sterile; bacterial counts reveal that organisms are present but in very small numbers; the chyme may also contain spores and certain bacteria that are more or less protected against the digestive agents of the stomach. This protection is afforded by an outer covering of a chitinous nature (spores) or, as in the case of the tubercle bacillus, by a covering of waxlike material. It is believed that persons with strictly normal digestion are much less liable to infection by such bacteria as those of typhoid and cholera than persons with less active gastric secretion. When the acid of the gastric juice falls below the level at which it possesses an antiseptic action, various bacteria and yeasts grow in the stomach contents, producing by the resulting fermentation irritating organic acids and gases. It is under these conditions that yeasts, sarcinae, and lactic and butyric acid bacilli find in the gastric contents a suitable nidus on which to grow.

The Amount of Acid (Gastric Analysis).—It has long been known that considerable variations in the amount of hydrochloric acid in the gastric juice may occur not only in disease of the stomach itself but also in general diseases, such as certain forms of anemia. On this account, a more or less elaborate technique has been developed for the purpose of determining the degree of acidity and the concentrations of hydrochloric acid and chlorides in the gastric contents.

The Fractional Test Meal and Related Techniques

The first step in this procedure consists in passing down the esophagus a tube of narrow bore (Rehfuss or Ryle tube), provided at its end with an oval tip in which are wide slots. The tube is so narrow that it can be left in position for several hours without discomfort. It is passed in the morning before any food has been taken; and by means of a syringe attached to the outer end, the residuum of the stomach contents is removed by aspiration. The volume obtained should not amount to more than 50 ml. One pint of thin oatmeal gruel, or of water, is then swallowed, and samples of 5 or 6 ml. each are subsequently removed

at intervals of fifteen minutes during a period of one or two hours. After aspirating each sample, a little air is blown down the tube so that what is left in it may be returned to the stomach. The amount remaining in the stomach after the period of observation is aspirated as a whole. The residuum, each of the samples, and the remainder are then examined for free acidity (free HCl), total acidity, total chlorides, and peptic strength. The older methods employed test meals of different kinds. The newer techniques make use of the drug histamine which has been found to be a potent gastric secretagogue, acting particularly on the acid secreting mechanism. When histamine is used, the drug is injected after the stomach tube has been swallowed and the contents of the resting stomach removed. Some clinicians favor the use of a dilute alcohol test meal. It would be out of place to describe the analytical methods in detail here, but the general principles are as follows:

Free Acidity.—This is due to hydrochloric acid which is not combined with protein. It is determined by titration with standard alkali in the presence of an indicator which changes color at the pH at which the HCl-protein compounds begin to dissociate. This titration value is therefore proportional to the pH of the solution as determined electrically or colorimetrically. The most convenient method is to titrate a measured sample of the fluid (2 ml.), to which a drop of Töpfer's indicator (methyl yellow) has been added, with 0.1 N NaOH until the pink color gives place to an orange one. This change occurs at a pH of about 3.6, and the results are expressed as the number of milliliters of 0.1 N NaOH required to neutralize 100 ml. of the stomach contents (i.e., multiply the milliliters of NaOH used by 50). When a gruel not containing protein is used as the test meal, this method is as accurate as need be for practical purposes, but when protein is present, the results may be too high because some of the protein-HCl compound becomes dissociated near the end point.

Total Acidity.—A drop of phenolphthalein solution is added to the above solution and titration with 0.1 N NaOH is continued until a pink color develops. Normally, only about 10 ml. per 100 ml. of stomach contents is required.

Total Chlorides.—The above fluid is mixed in a small evaporating dish with 5 ml. of HNO_3 (conc.) and 5 ml. 0.1 N $AgNO_3$ solution. After standing a few minutes, so that the precipitate of AgCl may settle, some powdered iron alum is added and the amount of free silver remaining in the solution is determined by titrating with 0.1 N thiocyanate. A pink color develops when all free silver has been precipitated by the thiocyanate. By subtracting the milliliters of thiocyanate used from 5 ml., we obtain the milliliters of 0.1 N $AgNO_3$ which has combined with the chlorides, and since 2 ml. of the stomach contents were used, this multiplied by 50 gives us the milliliters of 0.1 N chloride in 100 ml. This value multiplied by 0.00365 (the molecular weight of HCl) gives us the grams HCl per cent of stomach contents.

Mineral or Neutral Chlorides.—The above procedure is repeated on another sample of stomach contents after it has been evaporated to dryness and incinerated. The incineration drives off the HCl which is not combined with inorganic bases. By subtracting the mineral or neutral chloride from the total chloride, the amount of HCl combined with protein is obtained.

Peptic Strength.—Probably the method most commonly used is that of Mett. Egg white is drawn up into narrow glass tubes and coagulated by heat. A piece of the tubing is then incubated with the gastric contents and the length of the column of egg white which has become digested is measured. It is considered that the length of the column digested is proportional to the square root of the peptic strength. A newer and much more delicate technique is that perfected by Gilman and Cowgill[46] based on the digestion of the protein emulsion of an exposed x-ray film and measurement of the transmissibility of light by the film before and after the digestion.

In normal juice the total acidity steadily rises during the first hour until it reaches about 60 ml. N/10 acid per 100 ml. of juice. It then falls off and is back to 20 or less in a little over two hours. The free acidity is lower and is usually about 20 ml. less than the total in one hour, approaching closer to it in the later fractions. The pH is subject to some variations depending upon the conditions under which the juice is collected, whether the secretion of mucus is stimulated, how much saliva is swallowed and intestinal contents are regurgitated. A rather common finding is a pH of about 1.6-1.8.

When gastric juice is collected through a fistula from an empty stomach, or following histamine injection, or when a nonprotein test meal is given, very

little difference will be found between the free hydrochloric acid and the total acid; that is, between the results obtained by the second and the first of the methods described above. This is because in such juice there is little or no organic matter capable of combining with the hydrochloric acid, mucus being about the only such substance available, and there are no other acids, such as lactic or butyric, which might be produced by fermentative processes. The difference between the two titrations, however, becomes marked when protein food is undergoing digestion in the stomach.

The pathological condition in which there is most definitely a diminution of the hydrochloric acid is cancer, either of the stomach itself or, occasionally, of some other part of the body. In this disease there is invariably an appreciable amount of lactic acid, and some clinicians have gone so far as to claim that every case which yields no evidence of ability to secrete hydrochloric acid but does show lactic acid in the gastric contents is a case of cancer. Histamine has been shown to be of particular value in detecting only a slight ability to secrete hydrochloric acid, and therefore is useful when dealing with borderline and doubtful cases. As already indicated, the presence of lactic acid in the gastric contents has been considered as diagnostic of cancer by certain observers, the acid being considered as the product of a "deranged metabolism" of the cancer cells, but the work of Robertson, described in his monograph (1931), has demonstrated conclusively that this lactic acid is not the dextrorotatory variety found in muscle tissue but the inactive form produced by fermentative processes; by washing out the stomach thoroughly, no further lactic acid is produced until a period sufficient for the development of fermentation has elapsed. In pernicious anemia there is also a marked decrease in gastric acidity. In cases of gastric and duodenal ulcer there is usually a considerable increase.

In this connection it is pertinent to call attention to the common use by clinicians of the term *hyperacidity* to describe conditions characterized by unusually high acidity of the gastric contents. To the extent that the term is taken to mean that the gastric juice elaborated by the glands has a higher concentration of acid than normal, its use is most incorrect. Hollander and Cowgill[58] have shown that hydrochloric acid is normally formed by the cells at a remarkably constant and low pH, this being 0.90 (± 0.01). Therefore, there is no such thing as hyperacidity in the sense that the glands produce a secretion of abnormally high acidity. Carlson has suggested that the term *hypersecretion* more accurately describes the situation facing the clinician. The more or less continuous secretion of acid gastric juice without the usual neutralization of it should result in the finding that the gastric contents were always highly acidic. Excessive stimulation of the gastric glands through humoral factors, particularly those operating during the intestinal phase of gastric secretion (see page 910) could be in part responsible for this condition. The presence of acid in the upper intestine has been shown to stimulate gastric secretion. Discharge of gastric acid chyme into the duodenum together with failure of neutralization processes to function, could therefore operate to promote further secretion of gastric juice. Exclusion from the intestine of the alkaline pancreatic juice could result, theoretically therefore, in gastric hypersecretion. Fauley and Ivy[38] have tested this hypothesis in dogs with a Pavlov miniature stomach and found that such a hypersecretion does occur.

The Source of the Acid.—A question that has puzzled physiologists for many years concerns *the mechanism by which hydrochloric acid is secreted.* The percentage of hydrochloric acid in the gastric juice is considerably above that at which many living organisms can live (a fact demonstrated in part by the antiseptic action of the gastric juice) and yet this acid is secreted by the lining membrane of the stomach. How then do the cells of the gastric glands bring about the separation of this powerful acid from the perfectly neutral blood plasma? In the first place, it is significant that the mucous membrane of the stomach contains a higher percentage of chlorine than the average of other organs and tissues, indicating that it has the power of abstracting chlorine from the blood. The excess of chlorine in the mucosa must, moreover, be but a very small fraction of that actually secreted into the gastric juice. The chlorine content of the mucosa of the cardiac end is considerably greater than that of the pyloric portion of the stomach. These facts indicate that chlorine is attracted by the gastric cells, but they throw no light on the question as to where the hydrochloric acid is really formed.

It is quite well established that the hydrochloric acid is formed by the *parietal cells,* but the process by which these cells produce the acid and the question whether this is formed within the cell or by some chemical reaction in the lumen of the gland are unsolved problems. It has been argued that the latter process must occur, for otherwise the parietal cell would be destroyed by the strong acid. Against this view one may cite the studies of Dragstedt[32] showing that the gastric mucosa is not the only tissue capable of withstanding such high concentrations of acid. Dragstedt sutured various organs into incisions in the stomach wall and so exposed them to the acid secretion of the stomach. Such transplants of kidney, spleen, and other organs were found to be in a healthy state many months later, provided their normal blood supply had not been impaired by the operation; necrotic tissue was very quickly attacked by the acid. These observations should be of interest to the clinician because they show that the gastric acid is not per se a primary cause of ulcer.

The earlier work on this problem consisted of attempts to determine the locus of acid formation by microchemical precipitation of chlorine in the cells, by the staining reactions of the cells and by the formation of Prussian blue following the injection of potassium ferrocyanide and a ferric salt. All of the studies based on these methods have supported the view that the parietal cell is the cell of importance in the process, but that the final formation of the acid takes place in the gland lumen and not within the cell itself. The more recent work of Gilman and Cowgill,[48] suggesting that the concentration of the hydrochloric acid is dependent in considerable measure on the osmotic concentration of the blood, affords some support for another hypothesis. This postulates that the parietal cell secretes the acid as such but in very dilute concentration. As this secretion passes down the glandular lumen, water is actively absorbed by the gland cells as, for example, in the kidney tubule, but the mucosa cells are impermeable to the acid. This results in a gradual concentration of the acid, a process which can proceed, theoretically, until osmotic equilibrium with the blood is reached. Such a theory harmonizes well with the results of previous studies and does not seem to involve any wholly untenable assumptions. The reader will notice, however, that even this hypothesis does not completely explain the origin of the acid

within the cell. This might conceivably be due to certain peculiar properties of the membrane of the parietal cell permitting the transfer of both hydrogen and chlorine in ionic form.

Acid Responses in Human Beings.—In the average normal human subject a plot of total and free acid against time, following administration of the test meal or histamine stimulus, gives a curve characterized by a definite rise culminating in a peak or plateau and then a rather rapid fall. Maclean calls this type of curve an *isosecretory curve*. Some investigators hold that the curve for concentration of free acid gives just as much information of diagnostic value as that based on the total acid. In cases of so-called hypersecretion, the free acid continues to increase throughout the period of the test, often becoming as much as twice the maximum value commonly yielded by the normal subject. In hyposecretion the concentration of free acid remains low during the test or, if it increases at all, reaches a maximum that is far below that obtained in normal individuals. When endeavoring to interpret any given responses the student will do well to exercise some caution and to remember Carlson's statement that he has seen all of the supposedly significant curves obtained in clinical work duplicated in his laboratory in experiments on perfectly normal people. It should also be borne in mind that the various curves do not truly represent the actual amounts of acid secreted. To date no method has been devised that accomplishes this. During the period of the test, material has been discharging through the pylorus, and the amount discharged is undetermined. Furthermore, part of the acid in all probability is being constantly neutralized by regurgitation of alkaline fluid from the intestines. The extent of such neutralization can be estimated roughly by determining the amount of total chlorides in the gastric contents.

The phenomenon of maximum acidity has led to the suggestion that the stomach regulates the acidity by pouring out when necessary what has been called a neutralizing secretion in which the chlorine is present in the form of a neutral compound. The work of Maclean and Griffiths offered in support of this view has had extensive reexamination recently, chiefly in the studies of Wilhelmj and associates,[125] and those of Apperly and co-workers,[4] and is not confirmed; evidence is offered showing that regurgitation of alkaline material from the duodenum is the chief factor in regulating the acidity of the gastric contents.

The digestive action of hydrochloric acid is closely linked with that of pepsin, with which it will, therefore, be considered.

The Action of Pepsin.—A pepsin may be defined as a proteolytic enzyme which acts best in an acid medium. The pepsin of the gastric juice acts in conjunction with the hydrochloric acid. The enzyme is probably secreted by the chief cells of the gastric glands. Microscopic studies of the cells suggest that they elaborate pepsin in an inactive or precursor form called pepsinogen. Studies of extracts of the gastric mucosa also support this view. A water or glycerin extract of the tissue is not affected by treatment with alkali, whereas similar treatment of an acid extract results in a loss of digestive power. There is some evidence for the view that in nature there are different pepsins. Pepsin of the dog, for example, acts best in a hydrogen ion concentration corresponding to that of a 0.05 N. hydrochloric acid solution, whereas that of the human stomach works best at a concentration of 0.03 N. There are also certain differences with respect to the optimum temperature at which they act, and with regard

to the nature of the protein which they attack most readily. Although pepsin requires the presence of acid, this action of acid does not appear to depend solely on the hydrogen ion concentration; the other ion in the acid may play a rôle. For example, hydrochloric acid is much more effective than sulfuric acid, the SO_4 ion seeming to be unfavorable for some reason. There is evidence that the acid combines with the protein before the pepsin attacks the latter; for, if we first combine the protein with acid and then wash away all traces of free acid, the protein can be digested in a neutral pepsin solution without the liberation of any free acid. It has also been found that the pepsin becomes combined with the protein in the proteolytic process, for if elastin or fibrin is first immersed in a pepsin solution and then taken out and washed thoroughly to get rid of adherent pepsin, it will be found, on placing it in a hydrochloric acid solution of the proper strength, that peptic digestion proceeds. By means of such a method it has been possible to show that pepsin is present in intestinal contents and not immediately destroyed by trypsin of the pancreatic juice, as was formerly supposed.

Both pepsin and its precursor pepsinogen have now been isolated by Northrop and demonstrated to be protein in nature. Pepsins prepared from bovine gastric juice and pig gastric extracts in general show similar properties but can be distinguished by solubility measurements. "It is probable, therefore, that the various pepsins differ from species to species, as do the hemoglobins" (Northrop[98]). It is well for the student to bear in mind that crystalline pepsin differs from the crude preparations ordinarily used in digestion experiments in that the latter also contain another enzyme, gelatinase, which liquefies gelatin, and many so-called tests for pepsin really measure the activity of this gelatinase instead of the true pepsin.

Products of Peptic Digestion.—Pepsin does not completely disintegrate protein; it merely forms certain large molecular fragments which are still protein and quite complicated in nature. The first product is a metaprotein known as acid albumin or syntonin. This may be precipitated from the digest by careful neutralization of the acid. The next product is known as primary proteose; it is precipitated by half saturation with ammonium sulfate. The third product is secondary proteose, separated by complete saturation with ammonium sulfate. After all of these substances have been removed, there still remains in solution the fourth product—peptone—which, among other things, is characterized by the fact that with the biuret test it gives not a violet but a rose-pink color. It is important to note that the term *proteose* is a general one, and that it signifies in all probability a group of protein bodies falling within a certain range of molecular size, the molecules, however, being large enough to be salted out by increasing concentration of ammonium sulfate and other salts. Likewise, *peptones* constitute a group of proteins produced in the digestion, and characterized by another range of still smaller molecular size; in this case the molecules are too small to permit their removal by the salting-out process. Most of the commercial peptones are not pure preparations but merely mixtures of all of the soluble products of peptic digestion. This fact is not always appreciated by bacteriologists who use the commercial products in their experiments and erroneously refer their findings to true peptones. Along with the proteoses and peptones, a certain amount of free amino acids may also appear in peptic digestion. These facts, considered together with the observation that pepsin fails to digest the

largest synthetic polypeptide thus far prepared by the organic chemist, support the view that pepsin does not act primarily on peptide linkage but upon other types of chemical union existing in protein.

Under certain conditions the action of pepsin can be reversed so that proteoses and peptones are resynthesized into protein. This resynthesized protein has been called plastein,[119] it coagulates on heating and gives a biuret test like that of native proteins. Such a synthesis is theoretically possible if our current conceptions of the nature of enzyme action are correct, and the achievement of this synthesis therefore constitutes an interesting confirmation of these theories of enzyme activity.

Most, but not all, of the pepsin which leaves the stomach is destroyed in the intestine. A part of it may be absorbed into the blood and carried back to the gastric glands to be used again. This would account for the presence of antipepsin in the blood, and also for the presence of pepsin in the urine.

Clotting of Milk in the Stomach; Gastric Rennin.—Gastric juice has the power of clotting milk. Formerly it was supposed that this was due to pepsin, and it is true that all pepsins thus far tested have been shown to possess this property. It is also true that the acid alone will clot milk although study of the chemical changes undergone in the clotting indicates that the action of the acid is different from that of the enzyme. Hammarsten obtained evidence supporting the view that there is another enzyme besides pepsin in gastric juice endowed with the specific property of clotting milk. This precipitated a long controversy which seems to have been settled in favor of Hammarsten's theory. The enzyme is called *rennin*. During the clotting process rennin acts on the protein casein, splitting it to yield paracasein and whey albumose; the former, in the presence of calcium ions, is precipitated as a calcium compound. The prolonged controversy over the question of the identity of pepsin and rennin seems to have been caused by the fact that pepsin, although powerfully proteolytic, can clot milk to some extent, whereas rennin is extremely active in clotting milk but does show some slight proteolytic activity. The significance of gastric rennin is difficult to state. It has been argued that it is a decided advantage to the young nursing mammal to have the protein material of milk precipitated in the stomach; unfortunately, this fails to explain why rennin is present in the gastric juice of all vertebrates from the fishes to the primates. Bradley[15] suggests that both rennin and pepsin are parts of one large complicated enzyme complex, which undergoes a characteristic development, and in this way endeavors to explain the greater abundance of rennin over pepsin in the stomach of the young animal as compared with the adult. It is, of course, quite possible that rennin has some other as yet entirely unknown function; isolation of the enzyme in pure state and extensive studies of its properties would doubtless throw much light on this interesting possibility.

Other Digestive Changes in the Stomach.—

Gastric Lipase.—The gastric juice contains an enzyme which acts on fats, namely, gastric lipase. It is not very effective on such fats as olive oil, but on fats that are highly emulsified it is very active. The results of its action are the production of glycerol and fatty acids.

Intrinsic Anemic Factor.—In his studies of pernicious anemia Castle has been able to show that the normal stomach is able to produce some change in

meat (muscle) which gives it therapeutic value in the treatment of this disease; the stomach of the pernicious anemia patient is unable to bring about this change. In spite of much research on this question Castle and his associates have as yet been unable to relate this "intrinsic" biologic factor in gastric digestion to any of the known digestive agents. The discovery of its true nature therefore remains as one of the important objectives of future research.

DIGESTION IN THE INTESTINES

The further changes which the half-digested foodstuffs in the chyme undergo in the intestinal canal depend on the enzymes present in the secretion of the various glands and on the presence of bacteria. The most important of these secretions are the pancreatic and intestinal juices and the bile. The latter does not contain any enzyme, and in this sense is not a digestive juice; its influence on digestion is very great, however, because its constituents, the bile salts, greatly facilitate the action of pancreatic lipase as well as aid in the absorption of fats.

Pancreatic Digestion

The chief enzymes of the pancreatic juice are trypsin, lipase and amylase; erepsin is also present. The pH of the juice is over 8.5 and its titrable alkali about equals that of the acid of the gastric juice (about 0.1 N).

The Action of Trypsin.*—When the pancreatic juice enters the duodenum, it immediately develops powerful proteolytic powers, and this occurs also when "secretin juice" from the duct of the gland is mixed with an extract of the mucous membrane of the duodenum. This is due to the activation of trypsinogen to trypsin. A very small amount of the extract is capable of increasing the digestive activity of a very considerable quantity of pancreatic juice, and this property of activation is readily destroyed by heating the extract, showing that the action depends on the presence of an enzyme which has been called *enterokinase.*

On account of the large quantities of alkali in the pancreatic juice and bile, the acidity of the chyme is practically neutralized in the upper reaches of the intestine. A little lower down, however, an acid reaction may again develop. It is interesting to note that as a result of the great secretion of alkali by the pancreas, extracts of this organ after death show a very high degree of acidity in comparison with extracts from other organs and tissues. The activity of trypsin does not depend on the presence of free hydroxyl ions, as was previously supposed, but it may proceed in the presence of a decided amount of free acid. If pepsin is present together with trypsin in a distinctly acid solution, the pepsin seems to destroy the trypsin, unless the mixture contains a considerable quantity of protein, when the tryptic activity may persist even for several hours. Studies have also revealed the presence of trypsin in the stomach as a result of regurgitation of intestinal contents through the pylorus. A practical conclusion which we may draw from these results is that preparations of trypsin—the so-called *pancreatin,* for example—if given with the food, may pass in an active condition into the duodenum, where, in the

*It will be advantageous for the reader at this stage to review the chemical structure of proteins, fats, and carbohydrates, as outlined in the chapters on metabolism.

more favorable environment created by the neutralization of the excess of acid, it will develop its proteolytic power. The therapeutic administration of pancreatin is, therefore, justified (Long[76]).

Activated trypsin acts on proteins by breaking down many of the peptide linkages. The enzyme, therefore, acts in a different manner from pepsin. Thus, after tryptic digestion has proceeded for some time, only a trace of primary proteoses, but considerable quantities of leucine, tryosine, and other amino acids will be found present, although a good many peptide (NH-CO) linkages are still left unbroken, indicating that certain polypeptides are intact in the mixture. Free amino acids appear early in the course of tryptic digestion, and they accumulate until about one-half of all the peptide linkages of the protein have been broken down. To split the remaining polypeptides requires the aid of the erepsin, which is present in the mucous membrane of the intestine. A similar enzyme is also present in other tissues of the body. Interesting investigations have been made on the exact degree to which trypsin-enterokinase can split the various known polypeptides. This seems to depend upon the structure of the polypeptide molecule and on the number of amino acids present in the chain. For example, alanylglycine, but not glycylalanine is hydrolyzed, although both contain the same amino acids but linked together in a different way; and tetraglycylglycine, which contains five glycine radicles, is hydrolyzed, whereas diglycylglycine, which contains only three, is not. It is important to remember that erepsin cannot act on proteins which have not previously been digested by trypsin. It seems to act only on polypeptides and indeed it may be a mixture of enzymes specific for each polypeptide. It is now known that the complete hydrolysis of proteins by crude trypsin is due to a group of enzymes, namely erepsin, aminopolypeptidase, carboxypolypeptidase, protaminase and probably others, so that the idea of trypsin as a single enzyme responsible for all of the proteolytic actions exhibited by the pancreatic juice is incorrect.

The importance of the presence of *erepsin* in the mucous membrane of the intestine would seem to depend on the fact that it serves as a barrier to the passage of any unsplit polypeptides from the intestinal contents into the blood. It helps to insure that the protein molecule be broken into its ultimate units before absorption. Since the discovery of erepsin and its rôle in further reducing protein materials to their constituent amino acids, the tendency has been to emphasize the individual amino acids as the final products always obtained. This may involve some error. From the study of allergic phenomena it appears unquestionable that at least traces of certain proteins may escape more or less the digestive agents and be absorbed in the form of molecules large enough to produce allergic responses.

Studies of the autolytic digestion which takes place in organs kept in a sterile condition after death indicate tryptic digestion to be different from other types in that it produces only small quantities of ammonia. The large quantities of ammonia produced in autolytic digestion no doubt have a relationship to the acids simultaneously set free during the process.

A very accurate technique for measuring tryptic activity is that based on the principle of the Gilman-Cowgill[46] method for estimating peptic power in which the emulsion on an exposed x-ray film is digested and the transmissibility

of the film to light before and after the digestion determined. When making measurements of tryptic activity, a different set of buffers is used to produce a pH in the alkaline range, in contrast to the pepsin tests where the digestions are carried out at an acid pH.

The Action of Lipase.—Neutral fat is decomposed into fatty acids and glycerol by the *lipase* present in pancreatic juice. This enzyme may also be extracted from the glands by means of 60 per cent alcohol or by glycerol, but it is insoluble in water. It acts in alkaline, neutral, or faintly acid media, and its action is remarkably accelerated by the presence of bile, and considerably depressed by inorganic salts. This favoring action of bile is undoubtedly owing to the bile salts (see page 975), and it is probable that this action is dependent upon the influence which these have in lowering surface tension and emulsifying the fat and therefore bringing about a more intimate contact between fat and water. The further functions of bile in favoring absorption will be discussed later.

The Action of Pancreatic Amylase.—The action of pancreatic juice on starch depends on an *amylase*. In animals having no active ptyalin in the saliva, pancreatic amylase serves as the only agent for handling this important carbohydrate. In any case, at least for the first stages of the disruption of the starch molecule—that is, its conversion into the dextrins—pancreatic amylase is a more powerful enzyme than ptyalin. It does not appear to be as efficient as ptyalin in the final stages of the hydrolysis, for it does not produce as much reducing sugar. Indeed extracts of pancreas will sometimes convert starch into soluble starch and dextrin with great speed, but produce scarcely any reducing sugar. On this account it is believed by many investigators that there are at least two distinct and separate enzymes in pancreatic amylase and also perhaps in ptyalin, one a true amylase which converts starch into dextrins, and the other a dextrinase which converts dextrins to maltose. In the case of both ptyalin and pancreatic amylase digestion proceeds best in a very weak acid reaction. Amylase, as it is secreted into the pancreatic juice, is fully activated; bile, apart from the alkali which it contains, has no influence on amylolytic power.

Besides amylase the pancreatic juice also contains *maltase,* and in the case of young animals or of those that take milk with their food throughout their lives, *lactase* also. After the suckling has discontinued taking milk, the lactase disappears from the pancreatic juice. Attempts have been made to bring it back by feeding the adult upon milk but without success. Occasionally the pancreatic juice also contains *sucrase* which splits sucrose to yield its constituent monosaccharides.

Digestion by the Intestinal Juice

The following enzymes have been found to be present in the secretion of the glands in the wall of the small intestine: erepsin, sucrase, maltase, lactase, enterokinase, and nucleases. All but the last-named have already been referred to. The nucleases consist of a group of enzymes which act on nucleic acid and various degradation products of it to yield a variety of substances. Different members of the nuclease group are also found in various tissues of the body, and presumably play a rôle in the production of the nucleotides and nucleosides known to be important in special processes, such as muscle contraction, for ex-

ample. The fact that nucleases are provided in the intestinal juice suggests that nucleic acid itself does not readily pass through the intestinal mucosa, and therefore some disintegration of its molecule is necessary.

The Action of Bile

One of the main functions of the bile salts is in assisting not only in the digestion but also the absorption of fats. When bile is excluded from the intestine, the feces are found to contain large amounts of fatty acids which have been split off partly by the now less effective lipase and partly by the action of bacteria. The fatty acid thus liberated in the absence of bile salts is not absorbed, because the bile salts serve as the carriers of fatty acids into the epithelial cells and the lacteals. This they do by their hydrotropic action. The influence of bile salts in assisting the action of pancreatic lipase is probably due to a lowering of the surface tension, thus promoting a more intimate contact of water with fat. This accelerating influence has also been demonstrated with synthetic bile salts, showing clearly that it is really these and not any other constituents of the bile that are responsible for its accelerating influence.

Bile also plays a very important rôle as a *regulator of intestinal* putrefaction. In its absence the stools become extremely putrefactive and the individual suffers from severe constipation. Bile itself is a favorable culture medium for certain bacteria, and therefore its value in counteracting these conditions cannot be due to any antiseptic action. In all probability the favorable action of bile is due to its moderate laxative action, by which the intestinal contents are expelled before the bacteria have grown to any great extent in them. The favorable action of bile on the action of trypsin and pancreatic amylase appears to be due very largely to the alkali which it contains.

The bile also serves as a channel of excretion. It is the only body fluid which dissolves cholesterol to any appreciable extent, and this property is probably due to the presence of the bile salts. Many toxins, metallic poisons and metabolites have been shown to leave the body by way of the bile.

The Chemistry of Bile

Bile contains a variety of substances, both organic and inorganic in nature. It is not our purpose to discuss the chemistry of bile in great detail. It is pertinent to point out some of the peculiar features of bile composition. The most characteristic substances found in bile are the bile salts, cholesterol, and the bile pigments.

The Bile Salts.—In most animals the bile salts consist of the sodium salts of glycocholic and taurocholic acids. Each of these acids is composed of a part called cholic or cholalic acid which is more or less related in chemical structure to cholesterol, and of glycine ($CH_2NH_2.COOH$, amino-acetic acid), or taurine ($C_2H_7NSO_3$, amino-ethyl-sulfonic acid), a derivative of cysteine, which is α-amino-β-thiopropionic acid ($CH_2HS.CHNH_2.COOH$). The cholalic acids form a series, the exact acid in different biles not being necessarily the same; for example, that in the bile of the pig is different from that in man. Bile salts are produced only by the metabolism of the liver cells. This fact has been demonstrated in remarkable fashion by experiments on dogs, the livers of which have been removed by the ingenious operative technique of Mann and his

associates.[82] It is the cholic acid part of these compounds that is manufactured exclusively by the liver cells; taurine and glycine can be synthesized by other tissues.

The source of the taurine has been studied, because this substance contains sulfur and the sulfur-containing compounds present in protein, namely, cystine and methionine, appear to be essential constituents of the diet. It seems that taurine cannot replace cystine and methionine in the diet and that the body's store of taurine is limited; the formation of taurocholic acid is diminished if cholic acid is given for a considerable period without a concomitant administration of cystine; on the other hand, the supply of glycine appears to be inexhaustible, as this substance may be synthesized in the kidney from urea.

There is considerable variability in the relative amounts of taurocholic and glycocholic acids in the bile of different animals. Human bile contains a relatively small amount of taurocholic acid; on the other hand, the bile of the dog contains a large excess of it.

Cholesterol.—This is one of the sterols (solid alcohols). These substances are usually complex monohydric alcohols and are widely distributed in the tissues and fluids of both animals and plants (phytosterols). Cholesterol itself is an unsaturated secondary alcohol and is closely related to the coprosterol of the feces which, however, is saturated. It exists in the body partly in a free state and partly combined with fatty acids to form esters. There is considerable evidence that the concentrations in the blood of free cholesterol and the esters are influenced by changes in the intermediary metabolism of fat as well as in the transport of this foodstuff in the body. Cholesterol is highly insoluble in water; bile is the only body fluid which dissolves it to any appreciable degree. So far as we know, this cholesterol in bile is in the process of being excreted and represents that formerly present in broken-down erythrocytes and other cells; it is possible that some of it is exogenous being derived from the food. The cholesterol in bile is particularly important because it contributes to the formation of gallstones, from which, in fact, the word cholesterol (solid bile) is derived; it may constitute from 20 to 90 per cent of the gallstone, the remainder being organic matter, such as epithelial cells, inorganic salts, pigment, etc. Evidently the animal body can synthesize cholesterol. This is indicated by the fact that the sterols in the feces of herbivorous animals are not the phytosterols of the plants which they eat but are derivatives of cholesterol; furthermore, hens continue to lay eggs containing cholesterol when fed on diets devoid of it.

The bile salts are hemolytic whereas cholesterol is antihemolytic. It is not inconceivable that this is related in some way to the fragility of the red blood cell and thus to the anemia problem. Another very important biological property of cholesterol and its related compound ergosterol, which was originally found in ergot, concerns its relationship to vitamin D (see page 828). Evidently there are several derivatives of these two sterols which have vitamin D properties.

The Bile Pigments.—The pigments of the bile are *bilirubin* and *biliverdin*. The latter is produced from the former by oxidation. If the oxidation is carried a stage further, a blue pigment called bilicyanin is formed. This process of oxidation can be observed in the ring test for bile pigment with fuming nitric acid. When bilirubin is reduced, urobilin, one of the pigments of the urine,

is formed. Bilirubin must therefore be considered as the mother substance of all these pigments, and it is of interest in connection with its derivation to know that it has the same empirical formula as iron-free hematin or hematoporphyrin, which is produced by treating hemoglobin with concentrated sulfuric acid. Experiments have shown that in albino animals the injection of hematoporphyrin seems to sensitize the organism to light. This suggests that in the formation of bilirubin from the hemoglobin of red blood cells the body produces hematoporphyrin which is toxic, and this is altered in some way to yield an isomeric compound which is nontoxic.

Chemical investigation has shown that bilirubin is built up from substituted pyrrols, of which four are probably contained in the molecule. The pyrrol group is also present in indole and tryptophane; it consists of four carbon atoms and an NH group linked together as a ring. Similar pyrrol derivatives can be produced by decomposing chlorophyll, the green coloring matter of plants. It is important to remember that bilirubin is acid in nature, and therefore can combine with alkalies to form salts. The relative amounts of bilirubin and biliverdin vary in the bile of different animals.

When these pigments enter the intestines, they are reduced to urobilin, part of which passes out with the feces, another part being absorbed into the blood and excreted in the urine. Part of that excreted in the urine exists, however, as a chromogen called *urobilinogen*. The urobilinogen is converted into urobilin by the action of oxygen.

CHAPTER LXVII

BACTERIAL DIGESTION IN THE INTESTINE

On an average diet, in twenty-four hours, the feces of man weigh about 100 grams, or after drying, about 20 grams. About one-fourth of the dry matter may consist of the bodies of bacteria. If plated out by the ordinary bacteriologic methods, however, it will be found that only a small proportion of these bacteria are living. The greater number have been destroyed, probably by the action of mucin in the large intestine. The nitrogen content of the feces amounts to about 1.5 grams a day, of which about one-half may be bacterial nitrogen. If the diet contains large quantities of cellulose material, as in green vegetable food and fruit, the mass of feces as well as the bacterial content may be considerably greater.

The foregoing facts indicate that very extensive bacteriologic processes must be going on all the time in the intestinal contents, and the question arises as to whether such action is beneficial or harmful to the animal economy. To answer this question interesting observations have been made on the growth and well-being of animals excised from the uterus under strictly sterile conditions and maintained thereafter on sterile food. Such observations made on guinea pigs have shown that the animals thrive and grow for a considerable time. Experiments carried out on chicks have not, however, yielded similar results. Chicks hatched out from the egg under strictly sterile conditions and then fed on sterile grain, do not thrive, but do so if the grain is mixed with a certain amount of fowl excrement. These two sets of experiments, apparently contradictory in their results, show that for certain groups of animals bacteria are required, but not for others.

It will be remembered that the size of the large intestine varies considerably according to the nature of the diet (see page 947). Animals taking great quantities of cellulose foodstuffs have very large ceca and very long intestines, whereas those which, like the cat, live practically entirely on cellulose-free food, have a rudimentary large intestine. The size of the lower intestine is obviously correlated with the presence or absence of cellulose in the food. It will be remembered also that the forward movement of the contents of the large intestine is very slow; indeed special provision is made, by the presence of the so-called antiperistaltic wave, to delay its movement. This suggests that an important digestive process must be proceeding in this part of the gut. In these ways conditions become established in the cecum for the active operation of bacteria. They attack the cellulose, and liberate the more digestible foodstuffs contained in the vegetable cells, also producing from the cellulose itself materials of nutritive value. The acids that are also produced by this process are neutralized by the carbonates secreted by the mucosa. In the ruminants bacterial digestion in the cecum is not relatively of such importance, because it takes place mainly in the paunch. The food mixes in this part of the stomach with the saliva, so that bacteria and ferments called cytases, contained in it, attack the cellulose, liberating the more easily digested foodstuffs enclosed within the cell walls. As this process goes on acids accumulate in the digestive mixture. The food is then returned to the mouth and chewed over again, after which it is swallowed into the main stomach, where it is digested.

The aid which bacteria render digestion depends therefore on the nature of the diet. Man, being omnivorous, stands midway between the two groups of animals discussed above. Although the cellulose contained in his food is not itself sufficiently digested to furnish nu-

triment, yet it is so far acted upon as to permit the rupture of the cell, the contents of which are then digested. The cellulose is, however, of value in furnishing bulk to the intestinal contents—"intestinal ballast" it is sometimes called.

In the small intestine of man there are bacteria capable of acting on carbohydrates and producing from them organic acids, such as lactic, acetic, etc. So long as a sufficiency of carbohydrate exists to encourage the action of these bacteria, others having an action on protein do not seem to thrive. It may be that this is to be accounted for partly by the production of acid substances by the carbohydrate fermentation, and partly by the fact that, as soon as the protein molecule is broken down by the digestive enzymes, its amino acids are absorbed. It appears, also, that the nature of the carbohydrate being acted upon plays some rôle. The acid-producing organisms—*B. acidophilus,* for example—thrive much better when lactose is present in appreciable amounts in the food; this is a specific effect, for other disaccharides do not favor the growth of the aciduric forms. If the stools contain a great abundance of *B. acidophilus,* 90 per cent, for example, they are not putrefactive, and therefore do not yield an offensive odor; furthermore, the production of intestinal gas is greatly reduced. There are probably also bacteria in the small intestine capable of splitting fat into fatty acid and glycerol, but practically nothing is known of their action. In the large intestine of man, there are also protein-digesting bacteria. These organisms belong to the class, of which *B. coli communis* is an example, the various members of which are known as facultative anaerobes because they can grow in the presence or absence of oxygen.

If bacterial growth is excessive or there is an insufficiency of carbohydrates in the small intestine, the bacteria attack the amino acids produced by the digestive enzymes and decompose them into products that may be toxic if absorbed into the blood.

BACTERIAL DIGESTION OF PROTEIN

From the standpoint of pathology, the most important action of bacteria is that which takes place on protein. Under anaerobic conditions the intestinal bacteria have in general the power of splitting off the amino group, deamination, whereas under aerobic conditions they split off the carboxyl group. The latter process may take place either before or after the removal of the amino group.

If oxidation happens *after* deamination, the products are not highly toxic and include phenol, cresol, indole and skatole, which are partly absorbed into the blood and partly excreted with the feces.

The fractions of those substances that are absorbed into the blood have their toxicity removed by conjugation mainly with sulfuric acid to form the so-called *ethereal sulfates.* A part is also combined with glycuronic acid. In the case of phenol and cresol this conjugation occurs immediately after absorption, but in the case of indole and skatole it is preceded by an oxidative process, converting these substances into indoxyl and skatoxyl, respectively. This detoxication process occurs in the liver, as has been shown by experiments in which this organ was artificially perfused outside the body. The sulfates are removed from the blood by the kidneys and excreted in the urine. The proportion of ethereal sulfates in this fluid therefore gives an estimate of the extent of intestinal putrefaction of protein. The indican, being readily detectable by the well-known

color reaction of Jaffé, serves as an indicator of excessive intestinal putrefaction. The indole and skatole which are not absorbed and detoxicated are excreted in the feces to which they give the characteristic odor. The source of the phenol is tyrosine and that of indole is tryptophan. The reader is referred to textbooks of biochemistry for information concerning the chemical process involved in the formation of phenol, indole and skatole.

If oxidation occurs *before* deamination, highly toxic substances called amines are produced. They are the so-called *ptomaines*. From alanine, ethylamine is formed; from tyrosine, hydroxyphenylethylamine; from histidine, iminazolylethylamine, and so on. The process of formation is illustrated in the accompanying formulas:

1. $CH_3 \cdot CH(NH_2) \cdot COOH = CO_2 + CH_3 \cdot CH_2(NH_2)$
   (alanine) (ethylamine)

2. $C_6H_4(OH) \cdot CH_2 \cdot CH(NH_2) \cdot COOH = CO_2 + C_6H_4(OH) \cdot CH_2 \cdot CH_2 \cdot NH_2$
   (tyrosine) (hydroxyphenylethylamine or tyramine)

3. $C_6N_2H_3 \cdot CH_2 \cdot CH(NH_2) \cdot COOH = CO_2 + C_5H_3N_2 \cdot CH_2 \cdot CH_2 \cdot NH_2$
   (histidine) (iminazolylethylamine or histamine)

Similar substances are very common among the metabolic products of plants; for example, they are present in infusions of ergot. They are also no doubt produced in the tissues of mammals, histamine being thus produced, as well as adrenaline which is the hormone of the medulla of the adrenal gland, and may be described as a methylated ethylamine derivative of tyrosine. It is therefore related to tyramine.

Physiological Effects of Bacterial Decomposition Products.—The great importance attached to these decomposition products of proteins depends on the fact that they have powerful pharmacological actions. Most of the amines when injected intravenously cause the arterial blood pressure to rise owing to constriction of the arterioles. This effect becomes more pronounced as the amine increases in molecular weight; for instance, ethylamine has a feeble effect, with tyramine it is marked, and with epinephrine it becomes maximal. This action simulates that of the sympathetic nerves so that it is called sympathomimetic. Not all amines develop this type of action. Some may bring about a lowering of the blood pressure; histamine, for example, causes the capillaries to become dilated. In larger doses, serious nervous symptoms and a condition of profound collapse are produced by amines. This has led several investigators to believe that the persistent occurrence of bacterial fermentation and the absorption of the resulting decomposition products of protein into the blood ultimately cause arteriosclerosis and the other symptoms that accompany senescence. It is difficult at the present time to evaluate such claims and beliefs.

If the ptomaines have formed in the food before it is eaten, the symptoms develop in from one to five hours after the meal, but if the decomposition occurs in the intestine on account of bacteria that are taken at the same time as the food, the ptomaines may not have developed sufficiently to cause symptoms until after twelve to forty-eight hours; sometimes, however, they develop in an hour or so. Prominent among the symptoms is usually diarrhea, which may be regarded as a protective reaction intended to remove the offending bacteria and ptomaines.

Actual infection of food with bacteria of the paratyphoid-enteritidis type is much more common than poisoning by substances (ptomaines) that have been generated in food before it is taken (Jordan). Meat, milk and other protein foods are usually the carriers of the bacilli, and in most of the accurately recorded cases the meat or milk was found to be derived from animals suffering from enteritis or some other infection. Sometimes, however, perfectly good food may become infected by handling.

The term *autointoxication* has been used frequently to describe the condition believed to be due to excessive intestinal putrefaction with absorption of the various products. It is not intended that this volume shall deal extensively with clinical medicine, and therefore extended discussion of autointoxication will be avoided here. We might point out, however, that the term toxemia is too often used to signify a condition that fails to fall clearly into any other category; the symptoms are not sharply defined but vague and indefinite. The earlier view, put forward by Metchnikov, that buttermilk is valuable because it supplies acid-producing bacteria to counteract the activity of the putrefying types, has had extensive reinvestigation by Rettger and associates.[107] These investigators have shown that the organism *Bacillus acidophilus,* a normal inhabitant of the intestine of the healthy breast-fed infant, can be implanted in the intestine of the adult by feeding the live culture along with one of the carbohydrates lactose or dextrin; in favorable cases the implanted organisms may be present to the extent of 90 or more per cent of the viable bacteria found in the stool. Foods play a rôle in this process, lactose and dextrin proving to be particularly valuable. Inasmuch as lactose is the carbohydrate found in milk, this food proves to be an excellent vehicle for the bacteria, hence the use of so-called acidophilus milk in the treatment of autointoxication, constipation, etc. The fact that lactose and dextrin are the only carbohydrates found to favor the implantation of *B. acidophilus* shows that the action is not due merely to the production of acid in the fermentation; many other sugars readily yield acid yet do not favor in peculiar fashion the growth of these organisms. Therefore the older view, that ingestion of a high carbohydrate diet should suffice to bring about favorable change in the intestinal flora, is inadequate. Acidophilus milk therapy has been found to be effective in many cases of diarrhea as well as of constipation; it may also be used to advantage in treating milk allergy.

The exact cause of the *toxemia that develops during high intestinal obstruction* has been a subject of debate. Whipple and associates[123, 124] have contended that a "perverted secretion" is formed, that a toxic proteose is produced and absorbed, and that animals can be immunized against this proteose. Such an immunological reaction has been denied by C. Dragstedt and Moorhead.[31] Another explanation is that offered by L. Dragstedt et al.,[34] who found that rapid distention of closed intestinal loops by secretion occurs in many cases to the point of perforation and peritonitis. When provision for the onward passage of the pancreatic juice and bile was made, Jenkins[66] found that closed loops of the upper intestine did not lead to such early death of the experimental animals. There is no doubt that the intravenous injection of commercial peptone results in a picture of toxemia, characterized by great increase in urinary nitrogen, sulfur and phosphorus, fall in blood pressure, failure of the blood to clot, etc.; but whether this picture is the same as that observed in animals with high intestinal obstruction is a question. The recent work of Dragstedt and Ellis[33, 35] indicates that failure of prompt resorption of the secretions of the stomach and pancreas produces equally profound disturbances.

The reaction of the intestinal contents has been studied by many investigators and found to undergo some variations. Long and Fenger[76] found that in man the contents of the duodenum vary from slightly acid to distinctly acid, depending upon the location of the end of the tube with reference to the pylorus; lower down in the duodenum the action was as frequently acid as alkaline, the degree of acidity, however, being so slight as to favor rather than hinder the digestive powers of the pancreatic juice. Using the intestines of slaughtered animals, it was found that the contents of the last third of the small intestine were often alkaline but might be more acid even than those of the first third, which were usually faintly acid in reaction. There were considerable variations, however. It has been found that the administration of lactose, which favors the growth of aciduric organisms, results in a more acid reaction in the lower intestine; in chicks, the use of lactose can bring about a definitely acid reaction in the ceca which is particularly valuable in preventing the growth of the pathogenic coccidia in this species. From these and other indications in the literature, it appears evident that the intestinal contents can show some variation in reaction, and the

character of the food eaten plays some rôle in producing this change. Some of these changes have been believed to be important in relation to the most effective utilization of ingested calcium, phosphorus, iron, etc.

We should not leave our subject without some reference to *the presence of vitamin B in the intestinal excreta.* If a rat is housed in a false-bottom cage which allows the feces to fall through, it is found that twice as much vitamin B_1 must be fed in the diet to meet the requirement of the organism. Coprophagy on the part of the rat is thus a protective reaction. There is evidence that the great growth of bacteria in the rumen of the stomach of ruminants is associated with the production of vitamin B which in turn is utilized by the host; by this arrangement, these animals are protected against the development of a deficiency with respect to this vitamin. Tests have also revealed that the vitamin B_1 in the stools does not represent an excretion of vitamin through the intestinal wall. In all probability the vitamin present in the intestinal excreta is that contained in the dead bodies of the bacteria, and is not the result of production of the vitamin and its discharge by a secretory process into the medium surrounding the bacterial cell. It has been found that the presence of fat, as well as particular carbohydrates, in the ingested food plays some rôle in this process, probably by affecting the growth of the bacteria themselves; also, that other members of the vitamin B complex are similarly affected.

CHAPTER LXVIII

ABSORPTION FROM THE ALIMENTARY TRACT

In a general way it may be stated that the function of digestion is to break the relatively complex molecules of which the organic foodstuffs are constituted into simpler ones which are capable of absorption. Proteins are broken down to amino acids or very simple combinations of them; fats are split to yield glycerol and fatty acids; the complex polysaccharides are decomposed to give a mixture of their constituent monosaccharides. This simplification might lead one to expect that the mechanism by which absorption occurs is one merely of physical diffusion, but it is much more than this, since an element of selective action also comes into play. This is evident even for inorganic salts and the simple sugars. For example, sodium sulfate is absorbed from a loop of intestine much more readily than sodium chloride, and blood serum is completely absorbed although, obviously, the osmotic pressure due to its solutes is the same as that of the blood.

ABSORPTION FROM THE STOMACH

From the experimental work done on this question, it appears that the stomach cannot be regarded as an absorptive organ. This problem has been studied in at least two ways. The pylorus may be occluded in anesthetized animals, the test substance introduced into the stomach and then the gastric contents examined after a period. Meltzer used this technique in demonstrating that strychnine, for example, is not absorbed in the stomach; only after the ligature around the pylorus was removed and the gastric contents allowed to pass into the intestine could the symptoms of strychnine poisoning occur. Another method, which is doubtless more physiological, consists in preparing a duodenal fistula in an experimental animal, a dog, for example, then feeding the test substance, and collecting for analysis all of the material discharged through the fistula. London has made many observations based on use of this technique. The facts concerning absorption in the stomach will now be summarized.

Water.—When given alone, water is practically unabsorbed in the stomach. It quickly passes through this organ into the intestine. We have already commented on the fact that liquids pass through the stomach much more readily than solid materials, and this fact is difficult to harmonize with the Cannon theory of acid control of the pylorus. It is well to bear in mind in this connection, however, that not all liquids escape absorption from the lumen of the stomach. Alcohol is absorbed to a considerable extent. Water mixed with alcohol in varying proportions appears to undergo some absorption along with the alcohol. This fact is of clinical interest. Many attempts have been made to secure absorption in the stomach of therapeutic agents that are sensitive to digestive enzymes, particularly those in the intestine, and in a large proportion of these experiments alcohol has been used as the important absorptive constituent of the solutions tried. Oral administration of insulin has been attempted by such means.

Carbohydrates.—It appears that for any of the common sugars to be absorbed from the stomach the solutions must be fairly concentrated (5 per cent or more). When one considers this fact together with the observation that of the common foodstuffs carbohydrates leave the stomach the earliest, it must be concluded that such an absorption of sugars is of little practical significance.

Proteoses and Peptones.—These substances are the result of peptic digestion of native proteins in the stomach. Therefore the question of their absorption is an important one and it has been investigated experimentally. From the work of London, who used dogs with a duodenal fistula, it appears that there is practically no absorption of protein or its digestive products in the stomach.

Fats.—Of the three common foodstuffs fat has been shown to remain longest in the stomach. This suggests that fat may be absorbed to an appreciable extent. If fat is held in the stomach for many hours, its escape being prevented by ligation of the pylorus, histological evidence of fat absorption through the gastric mucosa can be obtained (Inouye). The conditions of such experiments are so unphysiological, however, that this amount of absorption can hardly be regarded as significant. Under ordinary conditions, there is practically no absorption of fat from the stomach.

Salts.—Salts are only slightly if at all absorbed from the stomach. The concentration of the salt has been shown to be a factor. For example, Brandl has claimed that when the concentration of sodium iodide is 3 per cent or greater, appreciable absorption may occur. The presence of alcohol seems to facilitate this absorption. Under more physiological conditions, however, it appears that sodium iodide, and many other salts as well, is practically unabsorbed. This behavior of sodium iodide has been made the basis of a simple gastric motor function test.

Summary.—From the experimental work done on this question, it appears that the stomach cannot be regarded as an absorptive organ. Any absorption that has been shown to occur is so slight as to be of little physiologic significance.

ABSORPTION FROM THE SMALL INTESTINE

The methods described above in the discussion of absorption from the stomach have also been used to study absorption from the small intestine. Examination of the material discharged through a fistula at the ileocecal valve indicates that the absorption of the products of digestion through the wall of the small intestine is remarkably complete. Fatty acids and glycerol, the results of fat digestion, undergo synthesis into neutral fat during the absorptive process, the resultant fat being taken up largely by the lymph vessels. Carbohydrates pass into the blood as simple sugars, monosaccharides. Proteins are absorbed into the blood as amino acids or relatively simple combinations of them, the peptides. Water is readily absorbed. Inasmuch as the chyme passing through the ileocecal valve is always fluid or semifluid in nature, any absorption of water that takes place during the absorption of a meal may be compensated for, in part at least, by secretion of it in order to maintain the liquid character of the chyme. When water is taken to alleviate thirst, much of it is undoubtedly absorbed in the small intestine. Sodium chloride readily passes through the intestinal wall into the blood stream, and this passage does not

seem to be entirely a matter of simple diffusion due to difference in osmotic pressure or other purely physical causes. In view of the fact that studies have indicated some differences to exist in the mechanisms of absorption of water-soluble substances as compared with the products of the digestion of fat, it is pertinent to discuss these two mechanisms in some detail.

Absorption of Water-Soluble Substances.—It has already been pointed out that the intestine exhibits a remarkable selectivity with respect to the absorption of many materials. Perhaps the most striking example of this is found in the case of the simple sugars. This has been investigated by C. F. Cori and G. T. Cori,[26] who devised a method for studying the rate of absorption, which is far superior to that previously employed. In Cori's method, the entire gastrointestinal tract of small animals, such as the rat, is employed. The animals, kept for some time previously on a standard diet, are starved, either for twenty-four or forty-eight hours, after which 2 or 3 ml. of a strong solution of sugar are placed in the stomach, through a small flexible catheter which can be passed by way of the mouth. The rate of absorption is ascertained by subtracting from the amount of sugar that was given, the amount found by analysis of the gastrointestinal contents on killing the animals after varying intervals of time. Cori and Cori state that when sufficient sugar is given, the amount absorbed is constant from hour to hour, at least up to four hours, and they define as the *coefficient of absorption* that number of grams of sugar absorbed per 100 Gm. of body weight per hour. This is characteristic for each sugar, but it varies according to the time the animal was starved prior to giving the sugar. It is independent of the initial concentration of the sugar solution in the intestine.

For the monosaccharides the coefficients, determined after a starvation period of forty-eight hours, are as follows: *d*-galactose, 0.196 Gm.; *d*-glucose, 0.178 Gm.; *d*-fructose, 0.077 Gm.; *d*-mannose, 0.034 Gm.; *l*-xylose, 0.028 Gm.; and *l*-arabinose, 0.016 Gm. A high degree of selectivity, independent of molecular weight and definitely related to molecular structure, is thus revealed. The pentoses are absorbed at a rate which is about one-eighth that of the better known hexoses. It is evident that the slight stereoisomeric difference between glucose and mannose makes a sharp difference in their coefficients of absorption. The only possible source of inaccuracy in the Coris' method is destruction of the sugar by intestinal bacteria, but it is stated that this does not occur. These results are in sharp contrast with those obtained in a study of absorption from the peritoneal cavity. In this case C. F. Cori and Goltz found that the different sugars are absorbed at equal rates which diminish with time. Obviously the concentration affects the process. By analysis of the so-called free sugar of the tissues it was found that when different sugars are injected intravenously they pass very rapidly and at equal rates from the blood into the liver and muscles. It requires a shorter time for equilibrium to be attained between blood and liver than between blood and muscle; this difference is probably dependent upon differences in blood supply.

The rate of absorption of fructose from the gastrointestinal tract is less than half that of glucose. Consequently, the ingestion of a given amount of fructose might be expected to have less effect on the level of blood sugar than the taking of a corresponding quantity of glucose. Differences observed in blood sugar curves after ingestion of these sugars may be attributable, in part at least, to differences in speed of absorption and not wholly to a greater tendency for

fructose to be retained in the liver. This consideration casts some doubt on the validity of the fructose assimilation curve as a test of hepatic function.

The selective properties of the intestinal mucosa toward different sugars can also be demonstrated by the comparatively simple experiment of placing equimolecular solutions in isolated loops of intestine (of rabbit or cat) suspended in oxygenated Tyrode's solution at body temperature. The rate of diffusion can then be measured by determining the percentage of sugar in samples of the Tyrode solution pipetted off at intervals. So long as the loop remains alive, as evidenced by the presence of rhythmic contractions, it is found that glucose diffuses much more quickly than a pentose, such as xylose. As the strength of the glucose solution is increased, diffusion in a living piece of gut becomes progressively more rapid up to a certain maximal concentration which is about 3/4 mol (13.5 per cent) solution. It declines or remains steady at higher concentrations. In a dead piece of intestine the rate of diffusion is, of course, proportional to the concentration of the sugar solution. In a living gut pentose solutions diffuse out in proportion to their concentration.

It has already been stated that selective absorption by the intestinal mucosa applies to inorganic salts. In the case of these substances absorption may occur at one level and excretion at another. Thus calcium and iron are absorbed in the jejunum and upper reaches of the small intestine but excreted lower down; phosphate apparently is both absorbed and excreted readily at various levels of the gut.

Chemical change of a substance may occur during its absorption. This can be very readily demonstrated by the isolated living intestinal loop method described above. When a cane sugar solution is placed in such a loop, glucose and levulose diffuse out. If the loop be killed, cane sugar diffuses out. This effect cannot be due to the invertase of succus entericus but to the presence of the enzyme in the intestinal epithelium itself. Another instance of chemical change occurring during absorption is seen in the action of erepsin. This enzyme splits into amino acids the lower polypeptides which are the end products of the action of trypsin. Recent work by London and associates,[75] who used the angiostomy technique which permits the taking of samples of portal blood from the normal unanesthetized animal, shows that when a meal of protein is being absorbed, there is a considerable increase in polypeptides and related compounds in the portal blood. These findings suggest that proteins may not be absorbed simply as individual amino acids, as has been widely taught; either an appreciable fraction of the polypeptides are absorbed as such, or compounds of this sort are synthesized as the amino acids are passed through the cells of the intestinal mucosa. The latter possibility, if correct, would make protein absorption similar in part to that of fat.

The activity of the villi of the intestine has been studied. Wells and Johnson[121] have perfected a technique for observing the behavior of villi under various conditions. The mucosa of the intestine, as is well known, can function as both an absorbing and a secreting tissue. It appears that when it is in the normal resting state, the mucosa functions to absorb materials; when irritated locally by mechanical, chemical, or osmotic stimuli, hyperemia results, there is swelling of the villi, tonic contractions occur that are effective in impeding the venous and possibly the lymphatic drainage, and there is profuse secretion of fluid. Wells and Johnson suggest that secretion as well as absorption of

fluid is a physical process, and that transfer of fluid through the gut wall is regulated primarily by vascular reactions, both local and general. These studies have been extended by Nasset and Parry[96] to include determination of the rôle of pressure in the process. The absorption of glucose in aqueous solution was found to be independent of intraintestinal pressure between the limits of 5 and 25 cm. of solution below atmospheric. The secretion of sodium chloride and characteristic enzymes was found to increase in linear fashion with decreasing intraintestinal pressure. These results may help to explain some of the contradictory results reported previously; different workers may have had different pressure conditions operating in their experiments. There still remain unexplained, however, many features of the absorptive process.

Absorption of Fats.—As has already been pointed out, fat is digested by the lipases to yield glycerol and fatty acids. The fats are absorbed into the lacteal which lies in a central position in the villus, but the details of the mechanism by which they pass into the lacteal are not clear. The usually accepted teaching is that the fatty acids which are split off by the action of lipase are brought into a water-soluble state by the hydrotropic action of the bile salts (see page 975) and then enter the epithelial cells in solution where they recombine with glycerol to form neutral fat. The glycerol entering into this combination may have been absorbed as such, or it may have been produced by the animal itself, as is evidenced by the fact that neutral fat appears in the lymph of the thoracic duct after feeding a meal containing fatty acids, but no neutral fat and therefore no glycerol. It is possible that the body can make glycerol from glucose when the former is lacking in the diet. The synthetic process within the cells is possibly accelerated by lipase, at least it is easy to show that esterases, of which lipase is a type, can greatly accelerate the formation of an ester when added to a mixture of the alcohol and acid which form it. The reversible action of enzymes depends on the law of mass action. The difficulty of accounting for the synthetic action going on to any great extent in the presence of water may be resolved by supposing that the fat, as quickly as it is synthesized, is removed from solution, so that it can no longer have any influence on the reaction.

Whether this chemical theory of fat absorption be correct or not, there is one thing that is very evident as absorption proceeds, and that is the accumulation of fat in the epithelial cells. It occurs as fine particles which progressively become larger toward the base of the cells; the fat may even appear in the form of large globules. However packed with fat the cells may be, none is ever seen in the peculiar striped border which characterizes these cells. This fact is considered to show that the fat cannot have entered as such, but in solution. Another explanation, however, for the absence of fat from the free border of the cells is that this portion is composed of lipoid materials in which neutral fat is soluble, and that it is passed on to the underlying protoplasm where it is insoluble. That the free border is lipoid in nature is indicated by the fact that lipoid-soluble dyes, such as neutral red or toluidin blue, pass through it into the cells, whereas water-soluble dyes apparently pass between the cells, dissolved possibly in the water-soluble substance which cements the cells together.

There is evidence that the leucocytes can carry fat particles through the reticular tissue to the central lacteal of the villus. The exact details of this passage into the lacteal are not clear. Once inside the lacteal, the further

transference of the fat to the thoracic duct is readily accounted for. In this connection it is pertinent to remind the student, that studies of the thoracic duct lymph have shown that only about 60 per cent of the fat undergoing absorption is accounted for. This should doubtless be interpreted as meaning that this problem still calls for research. It has been suggested that contraction of the muscle fibers, running in the reticular tissue of each villus from the muscularis mucosae to the wall of the central lacteal, results in pumping of the lacteal fluid into the lymphatics of the mucosa. Such a mechanism is suggested by the anatomical arrangements, but recent observations[121] of the behavior of the villus during absorption of water-soluble materials do not support the "villus pump theory." Observations of direct absorption of fat by the villus apparently have not yet been made. Once the fat is within the lymphatics of the mucosa its onward flow is determined by valves, and it is probable that the segmenting movements of the intestine assist in maintaining the movement of the chyle, as the fat-laden lymph is called.

Attempts have been made to support the chemical theory of fat absorption by feeding a neutral fat possessing some characteristic that depends on the manner of union existing between fatty acid and glycerol, and then determining whether this fat appears in an unchanged condition in the thoracic duct. If it does, it must have been absorbed through the intestinal epithelium in an unbroken, unsaponified condition, for it is unlikely that in any resynthesis occurring in the intestinal epithelium the fatty-acid molecules would recombine with the glycerol molecules in exactly the same manner as before. There are, however, but very few qualities of neutral fats, apart from those of the fatty acids which compose them, by which they may be characterized. Optical activity has been suggested as a basis for the desired identification. Unfortunately, none of the ordinary fats is optically active, although from chemical considerations it is quite conceivable that some might be. Bloor prepared a synthetic isomannid-dilaurate which is readily absorbed and he found, on feeding it to dogs, that the chyle flowing from the thoracic duct did not contain any of it. This result confirms the previous work of Frank, who found that the ethyl esters of fatty acids are not absorbed unchanged. Had this occurred, as would be required by the physical theory of fat absorption, these fatty acids would have appeared in the chyle in optically active condition. A new possibility in this field is presented by the discovery of deuterium, the isotope of hydrogen, which can be detected when present in minute amounts. By synthesizing compounds containing deuterium and administering them to the living organism it has already been proved possible to show that the fat of the food, even when present in small amount, is largely deposited in the fatty tissues of the body before being utilized in metabolism.[128] The small supply of deuterium has made it necessary thus far to perform such experiments on mice. Artificial fats might be prepared containing deuterium, these fats administered by way of the alimentary tract, and the fatty chyle in the thoracic duct lymph examined for its content of the new isotope of hydrogen. Experiments of this sort might throw further light on the mechanism of fat absorption.

If resynthesis of neutral fat occurs during absorption, it is probable that its purpose is to permit a rearrangement of fatty-acid molecules to form a new fat which is more adaptable for use in the organism. The lecithins, which constitute the most important part of the fatty substances of the cell itself, are mixed glycerides, that is to say, compounds containing a variety of fatty acids. The rearrangement of the molecules of neutral fat which apparently occurs during absorption may be the first step in the transformation of fat into lecithin.

In order further to elucidate this question, Bloor has performed a number of interesting experiments in which the chemical properties of fats before and after absorption were compared. The criteria which he took were melting point, iodine number, and mean molecular weight. It was found that during absorption very considerable changes occur in these characteristics. The results therefore support the chemical rather than the physical theory of fat absorption.

Mineral oil is apparently absorbed from the intestine to some extent. Indeed Channon and Collinson[24] have actually succeeded in isolating 2 grams of liquid paraffin from the liver of a pig that had been fed this hydrocarbon, and

they showed that its absorption lowers the iodine value of the liver fat. Undoubtedly sterols, such as vitamin D, are readily absorbed. It seems highly improbable, if not wholly impossible, that chemical changes are indispensable for the absorption of such compounds. Logic, however, does not permit one to infer from this consideration that hydrolysis and resynthesis are not involved in the absorption of neutral fat. More pertinent to this question is the doubt cast by J. Mellanby on the belief that disruption of neutral fat is a necessary preliminary to its absorption; he has pointed out that there is no more lipase in the pancreatic juice of the cat than is required to produce enough fatty acid for the emulsification of the ingested fat. Some fat must therefore be absorbed directly and the hydrotropic influence of the bile salts is probably responsible for bringing this about. This view receives some support from the observations of Frazer[42-44] who devised a method for counting fat particles in the blood and reported differences in the blood particle counts in the systemic as contrasted with the portal circulation when olive oil, as compared with a mixture of fatty acids and glycerol, was fed to rats. Frazer interpreted his findings to mean that the portion of dietary fat which is hydrolyzed forms soluble complexes with bile salts and is absorbed into the portal circulation for storage or special metabolic transformation in the liver; the remainder of the dietary fat is absorbed without hydrolysis into the lymphatic system, and thus poured into the general circulation through the thoracic duct to be stored in the fat depots.

The absorption of fat is seriously impaired when the pancreas is removed. In depancreatized dogs kept alive with insulin for example, the feces are excessively fatty but become normal when pancreas is added to the daily diet. In man the absence of pancreatic juice is said to diminish the absorption of fat by 50 to 60 per cent. If the bile is also absent, the diminution amounts to 80 to 90 per cent, and in such cases the administration of bile or pancreas powder greatly improves fat absorption. Even when both bile and pancreatic juice are absent some of the fat is split and the feces contain fatty acid as well as fat. This is probably attributable to the action of small amounts of lipase present in the gastric and intestinal juices, but bile being absent, this fatty acid is not absorbed. From the work of Greaves and Schmidt[51] it appears that absence of bile interferes also with the absorption of fat-soluble vitamin A. These investigators studied the effects of various conditions, biliary fistulas, for example, on the requirement of the rat for vitamin A. Icteric rats had the same requirement as the normal animals, but failed to absorb as much when the dietary factor was administered by stomach tube. Essentially the same type of results with respect to the absorption of vitamin K has also been reported by Greaves.[50]

The observations of Flint[41] show that, provided they are fed properly, dogs tolerate quite well the surgical removal of as much as 60 per cent of the small intestines; curiously enough, they are unable to handle much fat. Evidently, then, the clinician cannot consider loss of pancreatic juice and bile as the only factors leading to interference in fat absorption; a certain amount of intestinal mucosa is important.

ABSORPTION IN THE LARGE INTESTINE

Knowledge of the extent to which absorption takes place in the large intestine is important because of its possible use in so-called rectal feeding. Water is readily absorbed from the lumen of the large intestine. We have seen that one

function of this part of the alimentary tract is to dehydrate the chyme, changing it gradually to the consistency of the feces. Sodium chloride is also absorbed. Inasmuch as bacterial action is most intense in this part of the gut, the products of bacterial action that get into the blood are doubtless absorbed largely from this region. There are certain important facts which bear on the rectal feeding problem. Fats and proteins are absorbed in such small amounts that it is useless for the clinician to attempt to administer these foodstuffs by way of the rectum. Glucose, however, is absorbed to a considerable degree when the concentration used is approximately 10 per cent. Coleman utilized these facts in developing his method for feeding patients with gastric ulcer.

Cowgill and Weinstein have recently studied the absorption of vitamin B placed in the large intestine of dogs provided with a valvular fistula of the large intestine. From their work it appears that the surgeon may administer this important dietary factor to a patient through a fistula of the large intestine, but that different sources of the vitamin show differences in effective absorption. For example, the artificial product formerly used as the international standard of vitamin B_1, a fuller's earth adsorbate, does not readily yield its adsorbed vitamin in the large intestine, in contrast to a solution of the vitamin which may also be given parenterally. Evidently, then, the clinician may administer vitamin B_1 to a patient with an artificial anus, but he should be careful to select a suitable source of the vitamin to use in such cases.

PART VII

THE ENDOCRINE GLANDS

By R. G. Hoskins

CHAPTER LXIX

HORMONES IN PHYSIOLOGY

The principle of the hormonal regulation of bodily functions was introduced into physiology relatively recently. It represents a special phase of chemical regulation comparable in principle to the chemotactic activities seen in the lowest forms of life, and as exemplified by the control of the respiratory center by acid metabolites. Unlike nervous regulation, that by hormones is necessarily generalized, because of the discharge of the active principles (*internal secretions*) directly into the blood stream and thence their distribution throughout the body. Such specificity of organ response as is manifested is secured by the special reactivity of the recipient organs.

The fundamental concept of hormone physiology appears in naive form in the early history of western medicine. Various diseases were believed to be due to lack of one or more mysterious substances supplied by the different organs. It followed that the resulting diseases were to be cured by supplying these lacking substances through ingestion of the organs themselves. This system of treatment came to be known as *opotherapy*. It was employed by Celsus and Dioscorides. Wolf's liver was used for hepatic disease, hare's brain for nervousness and the lung of the fox for respiratory disorders. As Paracelsus formulated the doctrine of opotherapy, "heart cures heart, spleen spleen, lungs lungs."

Modern interest in the internal secretions was aroused largely by the work of Brown-Séquard in 1889, though a considerable number of investigators had preceded him in the experimental field. Reviving the ancient doctrine of opotherapy this investigator was led to treat himself for general debility by injections of testicular extracts. His enthusiastic reports of beneficial results at once commanded worldwide attention.

The first to formulate the modern idea of endocrinology was Bordeu, a physician at the Court of Louis XV. Bordeu taught that each organ of the body is "the workshop of a specific substance which passes into the blood" and that upon these substances the physiological integration of the body as a whole depends. He described in some detail the secondary sexual changes that result from castration or ovariectomy. Berthold in 1849 was the first to make a formal experimental attack upon the problems of endocrinology. He restudied the effects of castration in fowl and discovered that the changes following that operation can be prevented by implantation of testicular tissue. Berthold inferred that the retention of the sexual characteristics was due to "the pro-

ductive relation of the testis, i.e., to its effect upon the blood and thence through the corresponding effect of such blood upon the entire organism.'' It was Starling who introduced the term *''hormone''* to designate the active principles of the endocrine glands. Its root meaning is ''excitor,'' but the term is in part a misnomer in that some of the hormones actually decrease functions. Sharpey-Schäfer[125] proposed to meet this difficulty by designating the internal secretions, as a group, by the term ''autacoids.'' Those which stimulate were to be called hormones and those which depress, *chalones*. The terms were somewhat widely adopted by British writers but have failed of general acceptance—largely, perhaps, because a single hormone, e.g.. adrenalin, can be either stimulating or inhibiting, depending upon the tissue affected.

The principal hormone-producing organs are the pituitary, the thyroid, the parathyroids, the adrenals, the pancreas, the stomach and intestines and the gonads. Recent work suggests that the pineal and the thymus glands may also produce true hormones. Until recently the endocrine organs were frequently designated as the *''ductless glands''* but the term is in part a misnomer since the pancreas, at least, has both ducts and endocrine functions.

Well before the advent of endocrine physiology, physicians were acquainted with several diseases now known to be due to glandular disorders. In 1786 Parry had come to recognize the chief features of *exophthalmic goiter*. Eight cases were collected by him and published after his death in 1825. In 1850 Curling observed that defective thyroid development is accompanied by certain of the manifestations now well recognized in the disease, *myxedema*. In 1840 Mohr reported a remarkable and fatal obesity in a woman who suffered from beginning imbecility, loss of memory, somnolence, and partial blindness. Postmortem examination showed degeneration of the pituitary body. The relation of the pituitary to gigantic stature was dimly apprehended by several physicians, beginning as early as 1784, and the specific relationship of this gland to *acromegaly* was clearly outlined by Marie in 1886. In 1849 Addison described the disease bearing his name and pointed out its dependence upon destructive changes in the adrenal glands.

The first actual demonstration of the physiological process of *internal secretion* was afforded by Claude Bernard who described the process in 1848. He discovered that the glycogen of the liver is discharged as dextrose directly into the blood stream. While the term, internal secretion, is no longer applied to indifferent substances like dextrose, Bernard's work is of outstanding importance to endocrinology, for it proved the possibility of the direct transference of chemical substances from organ to blood stream.

While no bodily function, apparently, is free of hormone control, those most notably so affected are the digestive functions, growth and reproduction. That hormone control represents a primitive mechanism is suggested by the fact that the internal secretions are interchangeable from one species to another. Thus insulin is quite as useful in the treatment of human diabetes whether it is obtained from the pancreas of man, ox or fish.

The hormones in some cases are fairly simple chemical substances; certain have been obtained as crystalline bodies, but others apparently are of protein nature and share in the complexity of the latter. Some are remarkably potent. Adrenalin from the adrenal glands can be shown to exert a definite effect in concentration as low as one part in four hundred millions. The

thyroid hormone is so potent that two milligrams suffices to increase the oxidative processes of an adult by one per cent. It is estimated that one gram suffices for a human being for five years.

The practical application of endocrinology in the treatment of disease lags far behind the available anatomical and physiological knowledge. The therapeutic use of thyroid, insulin, adrenalin and posterior pituitary extracts has often been conspicuously successful. On the other hand, the administration of parathyroid extract, extract of adrenal cortex and various hormones related to the reproductive functions has often been disappointing. Other preparations that have shown potency in laboratory experimentation have as yet had only limited use in human disorders. Endocrine research, however, must be judged not only by its immediate practical utility, but also by the light which it has thrown on disease processes in general. As Barr[14] says, "With increasing knowledge of the hormones, many common symptoms and maladies have acquired new interest. Ideas concerning pathogenesis have been transformed and previously unrecognized interrelationships have been revealed. Adiposity, hypertrichosis, abnormal pigmentation, hypertension, menstrual disorders, disturbances in carbohydrate metabolism, decalcification of the skeleton and polycythaemia are a few of the pathologic states in which endocrine influences can be demonstrated."

In their control of the bodily functions the hormones operate in three different ways. Some influence the tissues directly; for example, the mammary glands react to certain endocrine influences when all nerve connections are cut. A hormone from one gland may importantly determine the secretion of another; the most notable example of this is the influence of the anterior pituitary on the gonads, the thyroid and the adrenal cortex. Finally, hormones may act through their influence on the nervous system.

The control of hormone secretion has presented a difficult problem and one concerning which our knowledge is still seriously defective. In general, the endocrine glands seem to be capable of a considerable amount of autonomous activity, but their secretory level is likewise subject to a considerable amount of adaptive control. In addition to regulation by other hormones, as previously mentioned, nervous impulses have also been shown to be important in certain cases. The fact that a thyroid graft, for example, suffices to forestall symptoms of hypothyroidism suggests that one of the factors in holding the secretory rate at the optimal level might be something akin to the law of mass action, the level of output representing an equilibrium between "secretion tension" and quantity of hormone in the circulating medium.

A topic which has received little consideration and which is of fundamental importance in endocrine physiology concerns the factors determining the reactivity to a given hormone. Fragmentary evidence indicates that some of these factors are the pH of the reacting tissues, the temperature of the tissues or of the environment, the age and sex of the subject, the nutritional condition of the tissues and the available supply of vitamins. The electrolyte balance seems also to be of importance.

Some factors which probably influence both the tissue reactivity and the level of hormone production in the various glands are season, diet, environmental temperature, age, sex, the levels of activity of related glands and phases of the sex cycle. These aspects of endocrinology are all in need of further investigation.

The proof that any given bodily structure has an endocrine function presents a difficult problem. The conventional first step toward that proof is to extirpate the organ in question and note the changes produced. These could be due to the absence of a hormone or to a failure to remove from the blood stream one or another deleterious metabolic product. That is to say, the structure might function either by a process of addition or subtraction. Another classic approach is to administer gland substance or an extract of the organ. This method has the logical defect of not excluding chemical artifacts as the source of any reactions that may be observed. The precursors of the hormones may be highly labile and either postmortem changes or chemical manipulation may alter them into pharmacologically active substances that are significantly different from the true hormones. Strict logic requires that the hormone be identified in the blood as it emerges from the gland but with one or two notable exceptions this has not been technically practicable. The chief reliance of endocrinologists, therefore, has been a combination of the first two methods; namely, to demonstrate changes following removal of the given organ and restoration of the affected functions to normality by so-called "replacement therapy" with glandular derivatives. This combined method largely meets the logical necessities in fixing the status of any given derivative though it does not prove the exact identity of the derivative with the actual hormone in question. The possibility remains that the derivative may serve only as a precursor substance from which the body is able to derive the hormone. The method is chiefly defective as a means of determining the total hormonal activity of a given organ. In no instance do we yet know all of the results of any gland extirpation whereas logic requires that all perturbations be corrected by the replacement therapy. Certainly mere "survival tests" which are often relied upon are inadequate even though the experimental animal seems to maintain good health. Complete restoration of all functions to normal is the crux of the matter.

The literature of endocrinology has become extensive and is rapidly growing. A textbook discussion such as this can deal with but a relatively small proportion of the available facts. It should be regarded as only a means to orientation and should be supplemented by reading of the more exhaustive works. A few of these may be cited.[17, 39, 50, 57, 58, 69, 83, 125, 146]

An exhaustive bibliography of endocrinology is available in the *Index Catalog of the Surgeon General's Library,* supplemented by the *Quarterly Cumulative Index Medicus.* Several contributions in *Physiological Reviews* afford a considerable number of authoritative discussions of important endocrine topics. The same can be said of the successive volumes of *Annual Review of Biochemistry* and *Annual Review of Physiology.* The current literature is dealt with in the journals, *Endocrinology* and *Journal of Clinical Endocrinology,* which publish both original articles and abstracts. *Biological Abstracts* is another good source of information. Special monographs on the individual glands will be cited in subsequent sections of this discussion.

CHAPTER LXX

THE THYROID GLAND

The first significant experimental contribution to our knowledge of thyroid physiology was made by Schiff in 1858. He removed the thyroid glands from a series of animals and found that death soon ensued. But these observations made little impression on contemporary physiologists, who at that particular time "had little interest in biological researches or confidence in their results" (Meltzer); the fashion then was to try to explain all the phenomenon of life in direct terms of physics and chemistry.

It is to clinicians rather than to physiologists that we are indebted for our first practical enlightenment regarding thyroid functions. Gull, a surgeon, in 1873 reported the cases of five women whose puffy faces, bulky forms, scanty dry hair, and general lethargy were recognized as indicating a common disease process. Five years later Ord, who had made a study of such patients, secured an autopsy of one; from this it appeared that the thyroid gland was atrophic and that the general puffiness of the subcutaneous tissues was due to an accumulation of mucoid material. He therefore designated the new disease *myxedema*. At this time the introduction of antisepsis by Lister emboldened surgeons to begin to treat goiters by radical operation. In 1883 Kocher reported upon the after-effects of the complete removal of goitrous glands and emphasized the resulting interference with nutrition. Schiff was then led to extend his earlier experiments and learned that not only could various symptoms of myxedema be produced by extirpating the thyroid glands in dogs, but also that these symptoms could be ameliorated by thyroid grafts. Numerous other investigators soon confirmed Schiff's results in work on various animals.

Considerable confusion was caused in these earlier experiments by a lack of knowledge of the independent function of the parathyroids. Thus in carnivores, in which the thyroid and parathyroid glands are closely associated anatomically, tetany and other symptoms now known to be due to parathyroid deficiency were noted, whereas in herbivorous animals these latter effects were absent. It was not until Gley[51] recognized in 1891 the independent functional significance of the parathyroids that the paradox was explained.

Using the newly developed calorimeter, Magnus-Levy[95] in 1895 discovered that clinical hypothyroidism is characterized by a lowering of the heat production *(basal metabolic rate)*—in some cases as much as 40 per cent. A similar effect was soon found to be characteristic of thyroidectomy in animals. In most mammals, according to Marine,[96] the fall in heat production begins between the fifth and seventh days after the operation. It reaches its lowest level (minus 30 to minus 40 per cent) in from twenty days to two months. The depression persists throughout the remainder of the life of the subject except as it is mitigated by thyroid medication or by regeneration of thyroid remnants that may be left behind. The effects of the operation are more striking in young than in older animals. The lowering of metabolism in the young leads to deficient physical, mental and sexual development (vide infra). For the detection of

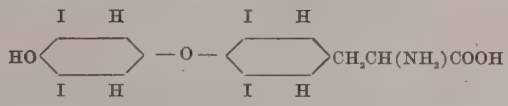
thyroid deficiency in clinical practice, determinations of the basal metabolic rate are of primary importance. In case of children in whom true "basal" rates are difficult to secure, the best index is the degree of skeletal development as brought out by skiagrams—especially of the wrists (Shelton[127]).

The thyroid is influenced by the nutritional state of the body. Excessive consumption of meat and, especially of liver, leads to overactivity; this, according to some authors, is followed by exhaustion of the gland and accumulation of colloid in its vesicles. Sea food, on the other hand, with its high iodine content, causes reduction in the size of the gland. Like proteins, fats also show a tendency to cause thyroid hypertrophy. Marine suggests that these reactions to food indicate that the thyroid hormone is more necessary to the oxidation of fats and proteins than of carbohydrates. Diets in which there is a serious imbalance of calcium and phosphorus together with iodine deficiency have been shown in dogs and rats to cause thyroid enlargement. On the other hand, general inanition causes involution of the thyroid with a decrease in the size of the epithelial cells and of the blood supply together with increase in the colloid and in the iodine store. These events are interpreted as indicative of decreased functional activity. Other evidence suggesting that the thyroid hormone plays a special role in the utilization of foodstuffs is that the "specific dynamic action" that normally results from their ingestion is materially lessened by thyroidectomy. The stimulating influence of food can be restored by thyroid feeding. Vitamin deficiency causes decrease in the size of the thyroid. This depression may be one of the mechanisms by which the nutritional manifestations of *avitaminosis* are brought about. The thyroid is susceptible to various other environmental influences. The gland is more active during the cold season and during periods of physiological stress such as puberty or pregnancy. Many cases of hyperthyroidism following emotional strain have been reported.

A special relationship between the thyroid gland and the element, iodine, has long been known. For more than a century the therapeutic value of iodine or iodine-containing substances in the treatment of goiter has been recognized. Several investigators in addition to Baumann[15] had made studies of the chemistry of thyroid substance but it was he who first (1895) was able to show that iodine in a firm organic combination is a normal constituent of this tissue. He treated the gland substance with 10 per cent sulfuric acid and obtained a brownish powder containing about 9 per cent of iodine which he named *iodothyrin*. He showed that the amount of iodine in the thyroid of dogs varies from one animal to another and that feeding iodine increases the amount. Four years later Oswald[107] observed that iodine is contained in the thyroid colloid and that the colloid is a globulin. He introduced the terms *thyroglobulin* and *iodothyroglobulin* which have since been much used in the literature. It was at first believed that these might represent true hormones of the gland. In man the thyroid gland contains as a maximum about twenty-five milligrams of iodine. In the calf this element has been shown to appear in the gland as early as the third fetal month. Seidell and Fenger[123] showed that there is a definite seasonal variation in the iodine content of the gland, it being relatively low in the spring and high in the late summer. The perfused living thyroid has been shown by Marine to have marked ability to select iodine from fluids circulated through it. The affinity of the thyroid for iodine can be shown also by feeding it to pregnant mothers and obtaining a

rapid storage in the fetal thyroids. Although iodine occurs in small amounts in various of the other endocrine glands, it is believed that the thyroid only has the ability of elaborating a hormone containing this element.

The next major step in the chemical investigation of the thyroid was reported by Kendall[77] in 1916. By means of alkaline hydrolysis he obtained a crystalline compound containing 65 per cent of iodine and showed that it produces various of the same pharmacologic effects as does thyroid substance itself. This compound he named *thyroxine,* a word coined from selected letters of the term "trihydro-tri-iodo-oxyindole propionic acid" which, he believed, represented the true hormone. In 1926 Harrington[59] improved the method of extraction and was able to secure better yields. He determined the empirical formula to be $C_{15}H_{11}O_4NI_4$. Structurally it is a tetra-iodo substituted derivative of the p-hydroxyphenyl ether of tyrosine or 3 ; 5 ; 3^1 ; 5^1 *tetra-iodothyronine,*



It appears that the mother substance from which natural thyroxine is elaborated is *l*-tyrosine. Marine believes that the true hormone of the thyroid is the iodothyroglobulin of Oswald and that thyroxine is only the active chemical group of this hormone. There are, however, some slight pharmacological differences between the two. In his earlier studies Kendall had obtained a physiologically inactive iodine compound which Harrington subsequently showed to be di-iodotyrosine. The latter has estimated that about 40 per cent of the iodine is in the form of thyroxine and 60 per cent in the form of di-iodotyrosine. These two substances appear to exist in a balanced state, the equilibrium point of which varies somewhat under different physiological or pathological conditions. Salter[120] has been able to synthesize an active agent, presumably thyroxine, by peptic catalysis of di-iodotyrosine.

The relationship of iodine to the thyroid gland is of special clinical importance in the condition known as *colloid goiter.* This condition is endemic in various districts throughout the world. It is a disorder in which the acini of the thyroid become distended with colloid, and the lining cells are flattened (Fig. 350). The gland may thus come to have a relatively enormous size, weighing a kilogram or more. Despite a great deal of study, the etiology of colloid goiter remains to some extent uncertain but most investigators assign predominant importance to deficiency of iodine in the food and drinking water. Of recent years increasing importance has been ascribed to a defective iodine-calcium balance in the food. The weight of available evidence supports the conception that the goiter represents an adaptive reaction, the low quality of the secretion being compensated in some degree by excessive production. From the standpoint of physiology the disorder is best regarded as a special case of hypothyroidism. The symptomatology varies from practically nothing to the full-blown picture of thyroid deficiency (vid. infra). The subject has been interestingly discussed by Marine.[97]

The clinical significance of the thyroid hormone centers largely in its relationship to metabolism. In 1893 Friederich Müller[101] discovered that in exophthalmic goiter (clinical "hyperthyroidism") the nitrogen metabolism as shown

by the nitrogenous metabolites in the urine is increased. The same effect can be produced in the normal animal by administering thyroid substance or thyroxine. Two years later Magnus-Levy[95] showed that in clinical hypothyroidism the rate of oxygen consumption (basal metabolism) is depressed—in marked cases as much as 40 per cent—and that the low rate can be raised to normal or above by feeding the gland substance. Proteins, fats and carbohydrates all share in the augmented oxidation. The means by which the thyroid hormone brings about the increased oxidation is not known, but the small quantity of the hormone that is required to produce a major effect suggests the action of a

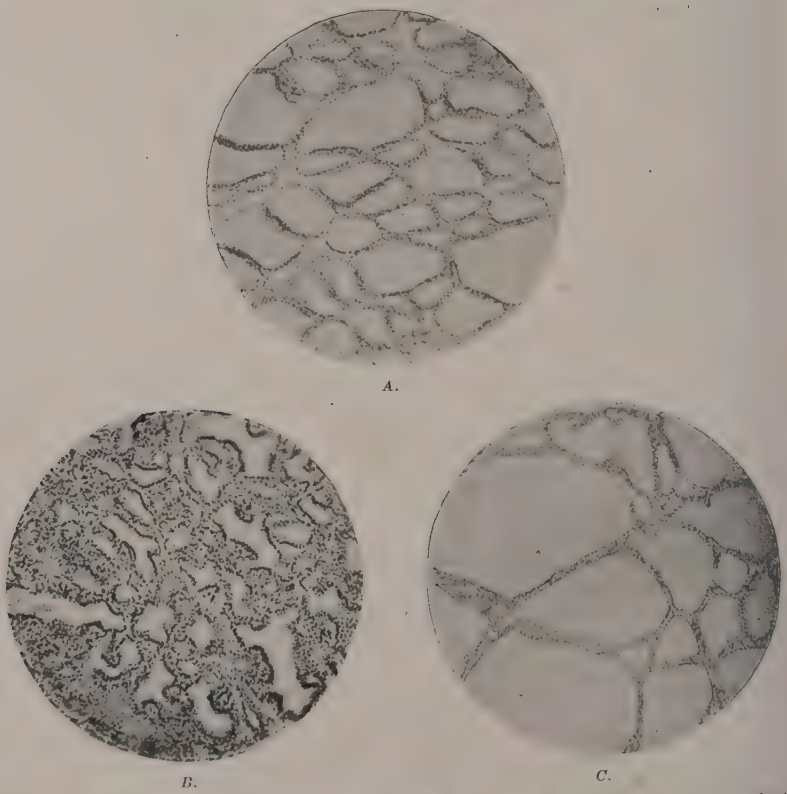


Fig. 350.—Microphotographs of thyroid gland of dog. *A*, normal gland; *B*, active hyperplasia; *C*, colloid goiter. (From Marine and Lenhart.)

catalytic agent. The influence of the hormone in the individual tissues persists for a considerable time as is shown by the increased oxygen consumption rate of surviving tissues taken from thyroidized animals. Conversely, as Ahlgren[4] has shown, muscles isolated from thyroidectomized animals consume much less oxygen than normal.

The thyroid hormone has an important influence on the processes of maturation and differentiation as contrasted with those of growth. The classic obser-

vation on this point is that of Gudernatsch[55] who reported in 1914 that the feeding of small amounts of thyroid substance to tadpoles results in their early metamorphosis to the adult form. Thus it is possible to produce a frog no larger than a house fly.

Another indicator that is sometimes utilized is the acetonitrile test of Reid Hunt[73] which depends upon the protection that thyroid hormone confers upon mice against this poison. It seems paradoxical that the same hormone decreases the resistance of rats, rabbits and guinea pigs to acetonitrile. The explanation has been offered that the reactions in both cases depend upon the increased metabolic rate of the recipient animals; in mice this leads to the production of an innocuous compound whereas in the other species the end-product is toxic.

Various other methods of assay are described by Munch.[102] Of recent years determinations of the iodine titer of the blood has been used clinically to some extent as an index of thyroid activity.[91]

It seems probable that physiological processes in general are stimulated by the thyroid hormone. This is indicated not only by the increased rate of oxygen consumption but also by the wasting of tissues and an increased reactivity of the nervous system. The stimulating influence is manifested in such symptoms of clinical hyperthyroidism as rapid pulse, insomnia and nervousness. The fact that the irritability of the sympathetic nervous system is increased is utilized in the "Goetsch test" for hyperthyroidism; a "positive" reaction amounts especially to an increased cardiovascular response to a standard injection of adrenalin.

Much of the physiology of the thyroid is exemplified in the symptoms of *thyroid deficiency* (hypothyroidism) in experimental animals or in man. When the deprivation is set up in infancy the most evident result is retardation in growth and development. When the gland is atrophied at birth the condition known as *cretinism** soon develops (Fig. 351). Ossification of the skeleton is retarded, hence bowing of the legs is common. Even though the cretin lives into adult years normal size is not attained. Brain development is sluggish with resulting deficiency of intelligence. The eyes are dull and lusterless and the face shows lack of animation. The human infant is slow in beginning to walk. The sex organs remain small and commonly fail to attain functional activity. The tonus of the muscles is low, a fact that accounts for the protruding abdomen that is characteristic of thyroid deficiency. This hypotonicity is shared by the smooth muscles, hence chronic constipation is common. The temperature of the body is somewhat subnormal and this is accompanied by a subjective sensation of chilliness. The skin is thickened and rather poorly nourished and the hair is coarse, sparse and dry. The teeth are slow in appearing and have little vitality; even with good dental care they are frequently lost. Commonly, though not always, the subjects are obese. Muscular activity is retarded. The reparative processes of the body are defective and wounds or fractures heal slowly. The activity of the red bone marrow is often depressed, leading to a condition of anemia.

Thyroid deficiency appearing at any age from intrauterine stage to adult years gives rise to the same general picture. The adult form of the disease is

*Meticulous writers prefer the designation, *childhood myxedema*, holding that the true *cretinism* of continental writers represents a special degenerative condition technically different from that of simple thyroid deficiency.

known as *myxedema.* In this the clinical manifestations of the disorder are, of course, modified by the fact that the patient has attained full stature and sexual maturity. Growth defects are not apparent, but disturbances of sex functions such as impotence, sterility and menstrual irregularity are important clinical manifestations. Various other clinical data bearing on thyroid deficiency are cited by Marine[96] and by Means.[100] Myxedema may occur spontaneously from thyroid atrophy, or it may follow the surgical removal of the gland. In the latter case "cachexia strumipriva" or "operative myxedema" is applied to the condition. Except in the mildest cases the signs are very characteristic. The skin is dry and thick, with a deposition of a fluid of high protein content in

Fig. 351.—Cretin, nineteen years old. The treatment with thyroid extract was started too late to be of benefit. (Patient of Dr. S. J. Webster.)

the subcutaneous tissues. (Ord introduced the term myxedema on the assumption that the edematous condition of the skin is due to the local accumulation of mucin.)

Quite distinct from the above described conditions of hypothyroidism are those produced by an excess of thyroid hormone in the blood; namely, *hyperthyroidism.* Hyperthyroidism may occur with or without ophthalmic symptoms, and it is rather widely believed that there are two distinct conditions associated with hyperfunction of the thyroid: (1) *Simple or "pure" hyperthyroidism* due to an adenomatous state of the gland (toxic adenoma) and which is associated

with symptoms that can be duplicated in animals by the administration of excessive doses of thyroid extract or of thyroxine; (2) *Exophthalmic goiter,* characterized in addition by ocular symptoms that cannot be accounted for by the action of the thyroid principle. The details of the symptoms and especially the nervous manifestations in the two conditions are said to differ significantly. The thyroid gland in exophthalmic goiter is enlarged, sometimes in one lobe only; it is hard and pulpy, and on auscultation a murmur is heard. Histologically the gland presents a picture of hyperplasia, that is to say, the vesicles have a deficiency of colloid material; their epithelium is columnar in type and their walls are thrown into folds.

Until recently the *control* of the thyroid gland has presented a largely unsolved problem. The evidence that clinical hyperthyroidism may be induced by emotional shock suggests that the gland is directly or indirectly under nervous control but numerous attempts to determine the secretory innervation of the thyroid have not given consistent results. The fact that a thyroid graft (which

A. *B.*

Fig. 352.—*A,* case of myxedema; *B,* same after seven months' treatment. (After Tigerstedt.)

is of course devoid of innervation) can maintain a thyroidectomized animal in good health indicates that nervous control is not primarily essential. This latter evidence suggests that the activity of the gland is in considerable measure determined by the composition of the blood. There is substantial evidence, as Collip,[30] Friedgood[45] and others have shown, that a major factor in the control of the gland is a special hormone—the *thyreotropic*—from the anterior lobe of the pituitary body. Following hypophysectomy or removal of the anterior lobe alone, a depression of the thyroid early ensues. Conversely, by the use of a special extract from the anterior pituitary, the thyroid can be thrown into a state of increased activity such as exists in clinical hyperthyroidism as seen in man. To what extent thyroid activity depends upon direct nervous or metabolic stimulation and to what extent such influences express themselves via the pituitary remains largely for further research to determine. It is probable that the reactions of the thyroid to such conditions as puberty, menstruation and pregnancy are mediated through the pituitary.

Various other interglandular relationships involving the thyroid have been postulated but the status of these is, in general, somewhat uncertain. The literature has been reviewed by Marine.[96]

In conclusion, the question may be asked, what is the adaptive significance of the thyroid? The fact that it is found as an active secreting structure in all vertebrates above the lowest fishes indicates that it subserves an important function. On the other hand, insects and various other invertebrates live efficiently without benefit of thyroid hormone. Even in the higher animals a considerable amount of biological activity persists in the absence of the hormone. It would seem well within the possibilities of evolution that an optimal degree of intrinsic tissue activity might have arisen without dependence upon this hormone. The fundamental biological significance of the gland seems to lie in its function of aiding the organism in adaptation to changing environment—external and internal—such as climatic alterations, dietary changes and such epochs of special stress as puberty and pregnancy. It is correspondingly probable that further studies of thyroid physiology will be most fruitful if addressed to these primary relationships.

CHAPTER LXXI

THE PARATHYROID GLANDS

The parathyroid glands appear first in the scale of life at the amphibian level. Embryologically they originate from tissue of the third branchial arch. It is a matter of ultimate physiological importance that the thymus also originates from this (and the fourth arch as well) whence it comes about that in its migration to its final position it is likely to carry parathyroid tissue with it. This explains why in certain animals aberrant parathyroids are frequently found as inclusions in the thymus. In the cat it has been reported to occur in 50 per cent of the subjects. Even in man parathyroid inclusions in the thymus have been reported by Brewer[20] to be of far more frequent occurrence than was formerly thought. Furthermore, the glands vary in their location in different animals even when normally placed. Thus a source of error difficult to control is present in experimentation. It is not improbable that much of the earlier work in which complete parathyroid extirpation was believed to have been achieved represented only various degrees of glandular deficiency. Thus may be explained various otherwise puzzling contradictions in the literature.

The fact that the parathyroid contains two distinct types of cells supports a surmise that the gland has at least two different functions. But only one is yet clearly known. Which cell type contributes the activity to the potent extract that is now in use is not known.

Parathyroids were first described by Remak in 1855 though credit for their discovery commonly goes to Sandström, who published (1880) a clear description of them but regarded them as merely displaced, undeveloped, fragments of thyroid tissue. Their independent functional importance was demonstrated by Gley in 1881. In an earlier paragraph mention was made of the confusion that arose in the earlier experimental work on the thyroid because of failure to appreciate the part played by the parathyroids.

Important evidence as to the functional significance of these glands can be obtained by studying the effects of their destruction, either experimentally in animals or inadvertently in thyroid operations in man. Under such conditions, commonly within less than a day, the blood calcium drops about one-third and tenseness with sensations of tingling or numbness begins to appear. Fine tremors can be detected in the muscles of the fingers or elsewhere. The tension increases and painful muscular cramps begin to appear in different parts of the body. At this time the blood calcium has further decreased to about 6 mg. per 100 ml. (the normal level is 10 mg.). Convulsive movements occur involving either single limbs or the entire body. Laryngeal spasm and marked cyanosis may arise requiring vigorous therapy to forestall immediate death. These manifestations mark the condition known as *tetany*. It may occur any time from sixteen hours to six days after the operation (Aub[12]). The tetany is due in part to increased excitability of the muscular tissue itself and in part to that of the nervous system. Since each muscular contraction multiplies the stimuli with which the sensitized nervous system is bombarded, a vicious circle is set up.

An important clinical manifestation of parathyroid deficiency is *chronic latent tetany*. Although the patient is free of the grosser manifestations, he

shows a general tendency to irritability, and by special tests, such as pressure or tapping over motor nerve trunks, muscle spasms can be induced. A lowered threshold to galvanic stimulation of nerve trunks is also demonstrable.

A subacute type of parathyroid deficiency has been reported by Shannon[124] who recorded the cases of eight children who developed convulsions followed by mental depression and irrational speech. The condition progressed to acute maniacal excitement with screaming, fighting, and tearing of the clothes. Terrifying dreams were common. In six of the cases the use of parathyroid extract was followed by relief of the symptoms. Whether day to day variation in placidity or irritability of normal subjects is in any measure determined by fluctuations in parathyroid secretion has not been determined.

The mechanism by which parathyroid deficiency produces increased neuromuscular irritability has not been adequately determined. It is not unlikely that the phenomenon is related to changes in cell permeability resulting from shifts in the titer of circulating calcium.

The foregoing manifestations are those most commonly seen. In other instances—in cats often and in dogs sometimes—instead of tetany a severe *progressive lethargy* supervenes. This is likely to be associated with marked malnutrition and early death. The factors which determine the kind of reaction are not well known.

The functional condition of the thyroid seems to play a part in the reactions to parathyroidectomy. With age, susceptibility to parathyroid deficiency decreases, and the symptoms become more easily controlled. The symptoms are made more severe by pregnancy, lactation, constipation, muscular exertion, infections, and fever.

The symptoms following parathyroid destruction are suggestively similar to those produced by strychnine, the toxin of rabies or of the tetanus bacillus. Although the symptoms are chiefly ascribed to disturbances of calcium metabolism there is some indirect evidence that intoxication may play a part. Koch,[78] and later, other investigators have isolated from the urine of animals in experimental tetany the toxic body, methyl guanidine. Injections of this substance into normal animals cause a marked increase of irritability which at least superficially resembles that of parathyroid deficiency. Unlike the latter condition, however, it is not relieved by treatment with calcium or parathyroid extracts. That intoxication of some sort plays an important rôle is indicated by the observations of Dragstedt,[36] who has found that withholding meat from the diet, preventing constipation, and administering lactose with copious quantities of fluid may serve to keep an animal in excellent health despite the destruction of all known parathyroid tissue. Such measures may be superior to the use of parathyroid extract in the treatment of clinical parathyroid deficiency.

The part that may be played in the tetanic manifestations by the acid-base balance of the body is not clear, though various writers have regarded it as important. By the administration of alkaline salts or, in susceptible subjects, by rapid breathing and by excessive vomiting, it is possible to obtain convulsions. This fact must be taken into account when clinical tetany suspected of being of parathyroid origin is encountered. Actually, in parathyroid tetany the body fluids are not usually unduly alkaline and at the height of the convulsions may shift definitely toward the acid side.

It is generally agreed that the most important factor in the production of parathyroid tetany is a disturbance of calcium metabolism and of the calcium-phosphorus equilibrium. The normal calcium titer in the blood is about 10 mg. per 100 ml. and that of inorganic phosphorus, 5 mg. That removal of the glands causes a marked fall in the calcium content of the blood has been frequently confirmed in a variety of animals. Conversely, parathyroid convulsions can be quickly checked by the injection of calcium salts. Calcium gluconate lends itself particularly well to this purpose though calcium chloride can be used if care be taken to prevent its escape into the tissue about the vein into which the injection is made. Luckhardt showed that if calcium salts are given by mouth in adequate amounts, parathyroidectomized animals can be kept alive and in good health indefinitely. After a time internal re-adjustment may take place rendering continuation of treatment unnecessary.[36]

How the parathyroid secretion functions in maintaining calcium equilibrium presents a difficult problem. It appears to act in part by controlling the absorption of calcium from the alimentary tract. The excretion of calcium is lessened by administering the parathyroid hormone, whereas destruction of the glands results in a severalfold increase of the excretion. The chief influence, however, of the hormone, so far as immediate influences are concerned, is regulation of the transference of calcium between the skeleton and the blood. Since thyroxine also has an important influence in the mobilization of stored calcium, it can be used as a useful adjunct in the treatment of parathyroid deficiency. Large doses of vitamin D are also useful to the same end.

This latter fact, together with the similarity between the symptoms of parathyroid deficiency and those of rickets indicates that there is a significant relationship between vitamin D and the parathyroid hormone, but details of the relationship are not clear. According to Aub[12] vitamin D when given in large enough amounts exerts much the same effects on the body as do parathyroid extracts. It raises the calcium level in blood; but, unlike the extracts, it also increases absorption of calcium from the intestinal tract. Vitamin D has certain advantages; it is effective by mouth whereas parathyroid extract must be given parenterally, and its effects are persistent. It has the disadvantage that it requires days to bring the subject under its influence, while parathyroid extract requires but a few hours.

A picture the converse to that of parathyroid deficiency can arise from hyperfunction of the glands or can be produced by the injection of parathyroid extracts. The method of producing potent preparations was discovered almost simultaneously by Hanson, by Berman, and by Collip in 1923-1924. The method is relatively simple; it consists in boiling the fresh parathyroid tissue in weak hydrochloric acid, neutralizing, and filtering. Rather pure extracts are now commercially available, but the hormone itself has not been isolated. Since the potency of the extracts is destroyed by peptic digestion, it is probable that the active principle is of protein nature.

The most striking effect of administering parathyroid extract is a marked increase in the blood calcium. The extract is most effective when administered by vein and somewhat less so when given intramuscularly. Oral administration is not effective. Following a single injection, blood calcium gradually rises for several hours, then gradually falls. If enough is given to increase the blood calcium level by half, vomiting may occur and the blood may show an increased

tendency to clot. With massive dosage the calcium titer may increase to as much as 23 mg. per 100 ml., often with fatal results during the second or third day. The viscosity of the blood rises to a point at which efficient circulation becomes impossible. Various species of animals differ in their susceptibility, dogs being highly responsive and rabbits almost indifferent as regards these deleterious effects. Associated with the increased blood calcium is a decrease in the inorganic phosphorus. Both elements are excreted in abnormal amounts, hence if the injections are long continued the body supply becomes markedly depleted. The trabeculae of the bones are first drawn upon and then the shafts. At the same time the activity of the osteoblasts is increased, and the blood phosphatase rises. A disadvantage in the clinical use of parathyroid extract in complete parathyroid deficiency is that the subjects gradually lose their reactivity to it; the dosage has to be frequently increased, and finally a stage is reached in which no dosage is adequate to forestall a fatal issue.

Although parathyroid deficiency has been known clinically for years, the opposite condition, *hyperparathyroidism,* has only recently become recognized as a definite disease. The disorder arises insidiously and becomes chronically progressive. It is characterized by early weakness and by pains in the bones, with increasing debility that ultimately brings the patient to a bedridden state. As the bones lose minerals they become softened and liable to fracture. The destructive process is irregularly distributed with a tendency to cyst formation. A certain degree of restorative activity accompanies the destructive processes with replacement of bone substance by connective tissue. The final condition in the skeleton is known as *osteitis fibrosa cystica,* a condition marked by generalized osteoporosis, cysts, and giant cell tumors. Anemia and hypotonia of both skeletal and smooth muscle are characteristic. Depression of excitability to the electric current is common. The blood calcium ranges abnormally high and phosphorus low. Both elements are excreted in excessive amounts. Deposits of calcium are likely to occur in the soft tissues and especially in the kidneys. Correlated with the resulting renal irritation is a tendency to polyuria with consequent polydipsia. Ultimately there may occur sufficient destruction of kidney tissue to lead to contraction and depressed function. As a result, nitrogenous waste products tend to accumulate in the body fluids.

As regards the *control* of parathyroid secretion little is known. Recent work indicates that the glands are in some measure controlled by a hormone from the anterior lobe of the pituitary. In certain hypophyseal tumors hyperplasia of the parathyroids has been detected; a similar condition has been produced by the injection of anterior pituitary extract. For the suggested hormone the designation, *"parathyrotropic"* has been offered, but there is some evidence that the principle having the activity mentioned is the "prolactin" of Riddle (see chapter on Hypophysis).

Presumably the parathyroid secretion is adaptively related to changes in environmental conditions and especially to diet, but details are lacking. Apparently the chief general significance of the parathyroid hormone is the facilitation of mobilization of calcium and phosphorus salts which, in their stored form, are chemically rather inert.

For further details regarding parathyroid physiology the excellent reviews by Thomson and Collip,[137] and by Dragstedt[36] may be consulted.

CHAPTER LXXII

THE ADRENAL GLANDS*

The mammalian adrenal is made up of two distinct parts, the *cortex* and the *medulla,* the functions of which are apparently independent. A frequently used synonym for the glands is "suprarenal," but since the structures lie *above* the kidneys only in the few animals that assume the erect posture, the term is largely a misnomer. In many vertebrates below the mammalian group the cortex and the medulla are represented by separate organs, the *interrenal bodies* and the *chromophil bodies,* respectively. Interrenal bodies are found as low in the scale of life as the cyclostome fishes. Chromophil tissue has been identified in several invertebrates—notably in the abdominal ganglia of leeches. For further details of the comparative anatomy of the adrenals the book by Grollman[53] may be consulted.

Embryologically the adrenals of man arise in close association with the primitive sex glands with which they are more or less associated functionally throughout life. That they play an important role in prenatal existence is suggested by their precocious formation; in the third month of fetal life they are the most prominent structures within the body cavity. At birth they are about a third as large as the kidneys but in early infancy a relatively thick zone lying between the medulla and the outer part of the cortex undergoes involution with consequent reduction in the size of the total gland. At this period hemorrhages within the gland take place with relative ease. The portion of the gland that thus undergoes absorption has recently been designated by Grollman[53] as the "androgenic zone." He regards it as a third independent entity having only the function implied in the name. According to Broster and Vines[23] the androgenic tissue can be differentiated histologically by its affinity for fuchsin dye.

Accessory cortical bodies have been described in various mammals and these are of importance to the experimental physiologist because, in operations designed to produce complete cortical deficiency they may be left behind and by their hypertrophy defeat the purpose of the experiment or lead to false conclusions. *Accessory chromophil bodies* are also of wide occurrence. The *carotid body* is of chromophil nature, and there are small masses of chromophil cells, the *paraganglia,* associated with the sympathetic nerve ganglia. The extent to which the accessory chromophil tissue may serve to complicate physiological experiments is somewhat uncertain, but satisfactory evidence of their having any vital role has not been adduced.

The size of the adrenals varies with a number of conditions. In some species they are proportionately ten times as large as in others. They become hypertrophic in fevers, after exposure to heat or to cold, in inanition, and in poor health. The adrenals of the wild rat are larger than those of the domesticated variety. In some species they are larger in females than in males. They also enlarge during pregnancy and retain the enlargement during the lactation period. In some species they enlarge in both sexes during the breeding season.

*This chapter deals chiefly with the adrenal cortex. The adrenal medulla, although a definite endocrine organ, may be considered, on embryological and physiological grounds, to be a part of the sympathetic division of the autonomic nervous system. It has been considered in Chapter XVI.

The hypertrophy under these various conditions is largely or entirely restricted to the cortical portion. It is probable that the hypertrophy is in considerable measure due to antecedent changes in the anterior pituitary.

ADRENAL DEFICIENCY

The adrenals were clearly described by Eustachius as early as 1563. Over the succeeding years various picturesque theories as to their functions were evolved,[69] but it was not until 1855 when their relationship to Addison's disease was discovered that their physiological significance began to be apprehended. This disorder, which is due to destructive lesions of the cortex, may be described in Addison's own classic words:[3] "The leading and characteristic features of the morbid state to which I would direct attention are, anaemia, general languor and debility, remarkable feebleness of the heart's action, irritability of the stomach, and a peculiar change of colour in the skin, occurring in connection with a diseased condition of the 'suprarenal capsules.' . . . This singular discoloration usually increases with the advance of the disease; the anaemia, languor, failure of appetite, and feebleness of the heart, become aggravated; . . . . the body wastes . . . . the pulse becomes smaller and weaker; and without any special complaint of pain or uneasiness the patient at length gradually sinks and expires."

Despite the assiduous efforts of many investigators since the time of Addison his contribution remains the most significant in the history of adrenal research. Relatively little that is fundamental in the syndrome of adrenal failure has since been added to the gross picture.

Shortly after the publication of Addison's monograph, Brown-Séquard[24] essayed to reproduce the syndrome experimentally. He removed the adrenals from dogs, cats, rabbits, and guinea pigs with results seemingly confirmatory of Addison's observations—marked prostration and early death. When shortly afterward, however, it was independently shown by two other investigators that rats were able to survive in good health after what appeared to be complete extirpation of the adrenals, confidence in Brown-Séquard's results was undermined.

Research on the glands then languished for forty years until interest was revived by the work of Oliver and Schäfer[105] in 1894. These investigators reported the discovery that adrenal extracts are characterized by "an extraordinary effect upon the tone of the heart and arteries, transcending that of any known drug." In the meanwhile the picture of adrenal deficiency had been shown to include marked weakness of the heartbeat and low blood pressure. These factors could well account for the accompanying prostration. Oliver and Schäfer's new observations therefore appeared convincingly to supplement the findings of Brown-Séquard and to indicate as the vital function of the adrenals that of sustaining cardiovascular activity (tonus). For the next two or three decades the "tonus theory" appealed to most physiologists as a satisfactory explanation of the *raison d'être* of the glands. Researches largely turned therefore to studies on the physiology of the medullary secretion, *adrenalin*. The outstanding addition to knowledge at this time was the fact that this substance has a highly selective influence on effectors innervated by the sympathetic nervous system (Elliot[38]). So intimate is the relationship that the physiology of the adrenal medulla can advantageously be discussed with that of the sym-

pathetic division of the autonomic nervous system (see Chapter XVI). For details regarding the effects of adrenalin on the various tissues and organs consult Sharpey-Schäfer.[125]

Early in the twentieth century, evidence began to appear which rendered the tonus theory increasingly untenable. Although the morphological pathology of Addison's disease remained a matter of dispute, evidence was gradually accumulating that it is destruction of the cortex rather than of the medulla that is etiologically important. The primacy of the cortex was largely determined by Biedl[16] when he discovered that in the skate, in which form the medullary and cortical homologues are anatomically separate, destruction of the interrenal bodies, leaving the chromophil bodies intact, results in death. One skate, in which a small proportion of the interrenal body was left, survived without symptoms. Several investigators, among them Biedl, then attempted to destroy either the cortex or the medulla in mammals, leaving the other moiety more or less intact. The accumulating weight of the evidence thus derived was supportive of Biedl's work on the skate. Mammals were frequently found to survive partial adrenal extirpation when only cortical tissue could be demonstrated in the persisting parts of the glands. From such experiments it appeared that health can be sustained in animals possessing no medullary tissue and as little as one-eighth of the normal amount of cortex. Certain investigators continued to hold, however, that the presence of extramedullary chromophil tissue in the animals vitiated such experiments.

In further attempts, then, to settle the functional significance of the medulla, attention was turned to a study of the properties of adrenalin in relationship to the "tonus" of sympathetically innervated effectors. It was noted that when the blood supply of the adrenals was cut off, thus suspending the secretion of adrenalin, no detectable disturbance in blood pressure occurred for a matter of hours, whereas the pressor influence of adrenalin is notably evanescent. If the function of the adrenals were to keep the circulatory system under "tonic" stimulation by secreted adrenalin the sudden withdrawal of this substance should have led to an immediate fall of blood pressure. The tonus theory in its simple form thus became untenable. The possibility remained, however, that adrenalin might have a more slowly acting influence leading to the same general end: it might play a necessary role in preserving the responsivity of the sympathetic nervous system. Researches by Hoskins and various collaborators[67] brought forth several facts incompatible with the tonus theory in either guise. It was found that when adrenalin was slowly infused by vein into animals showing effects of acute adrenal deficiency, there was no improvement in sympathetic reactivity. Indeed, in a considerable proportion of the experimental animals, the infusions served to depress the irritability. It was also noted that if adrenalin in high dilution were administered to a normal animal the effect was not, as theory demanded, to increase the blood pressure but to lower it. The depressor effect was shown to be due largely to selective vasodilatation in the arterioles of the skeletal muscles. It was also discovered that the motor functions of the gastrointestinal tract were suspended by adrenalin in smaller doses than those necessary to produce a minimal effect upon blood pressure. For further information regarding the physiology of the adrenal medulla the reader is referred to the chapter on the Autonomic Nervous System (Chapter XVI).

Adrenal Cortical Deficiency.—The remainder of this discussion will be devoted to the physiology of the adrenal cortex. Since studies aiming to elucidate this function are largely based, directly or indirectly, upon extirpation experiments, the results of these become a matter of paramount importance. Adrenal extirpations in the pre-antiseptic days were, of course, hazardous and for a considerable period after the publication of Brown-Séquard's work[24] it was a moot question whether the fatal outcome of such operations was due to an interference with gland function or to the surgical hazards. With the introduction of asepsis and the improvement of technique the matter became clarified. There is now no doubt that complete removal of all cortical tissue is a fatal operation. The time of survival can be extended by meticulous attention to operative technique and by utilizing a two-stage operation, allowing a few days to intervene between removal of the first and the second gland. Under such conditions the survival period, in the various laboratory animals, ranges from a few days to a few weeks. Ordinarily, if accessory cortical bodies are overlooked or if fragments of cortex are inadvertently left behind, the animal survives indefinitely because of the hypertrophy of these structures. Occasionally, however, the animal goes into a chronic, progressive, partial adrenal insufficiency from which it ultimately dies. Grollman emphasizes this phenomenon as offering a probable explanation for the apparent efficacy of inferior adrenal extracts in prolonging life.

Animals lacking their adrenals are highly sensitive to traumatic injury or hemorrhage. The survival period is significantly prolonged by keeping the animals in a warm environment. In general, young animals survive for shorter periods than adults, a fact probably correlated with their more rapid metabolic processes. Initial good nutrition and general good health are assets in surviving the operation. Expeditious operating with consequent shortening of the time of anesthesia prolongs the survival period, while excitement and exercise as well as high protein diets shorten it. There is some, but not concordant, evidence that pregnancy lengthens the survival period. Estrus, which leads to increased bodily activity, shortens the period whereas castration, which has the opposite effect, lengthens it. Any sort of infection or intoxication which depletes the vitality shortens the period. Presumably, all the conditions mentioned have their counterparts in patients suffering from Addison's disease.

In untreated, fatal adrenal insufficiency, the picture shown by various animals is roughly the same. After a brief stage of recovery from the operation the animal appears to be normal in every way. The wounds promptly start to heal and the subjects show a normal alertness and desire for food and drink. The blood pressure is normal and the chemical constituents of the blood preserve their normal relationships. But within a few days symptoms of insufficiency begin. The animal becomes apathetic, refuses food and not infrequently vomits bile or blood-stained material. Watery or bloody diarrhea is often seen. Muscular movements become slow and uncertain and not infrequently twitching or even convulsions supervene; a characteristic disturbance of gait often develops because of predominant weakness of the hind legs. Eventually, the animal becomes prostrated and will respond to only intensive stimulation. In warm-blooded animals the body temperature gradually falls, the skin becoming cold and the mucous membranes pale. In the acute phase respiration is rapid and then gradually becomes slow. Anuria may supervene. The animal finally falls into coma with respiratory paralysis from which death occurs while the heart is still beating.

During the first part of the postoperative period the arterial blood pressure is approximately normal but during the last two or three days of life it falls off at an increasing rate until, shortly before death, it is approximately half the normal level. The body temperature and the rate of oxygen consumption follow a somewhat similar course. The body weight begins to recede quite early and

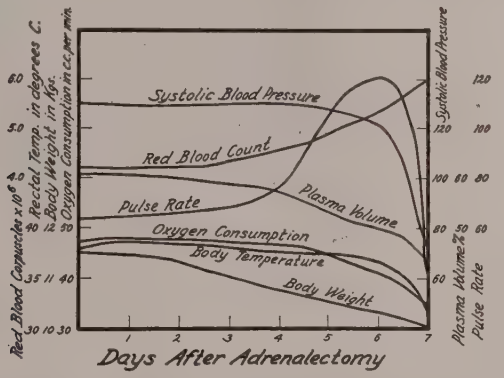

Fig. 353.—Changes in various physiological functions in adrenal insufficiency. The curves represent composite records of results obtained on dogs adrenalectomized in stages. The animals received no therapy during the period of study and died seven days following the removal of the second gland. (From Grollman: *The Adrenals*, Baltimore, 1936, The Williams and Wilkins Company.)

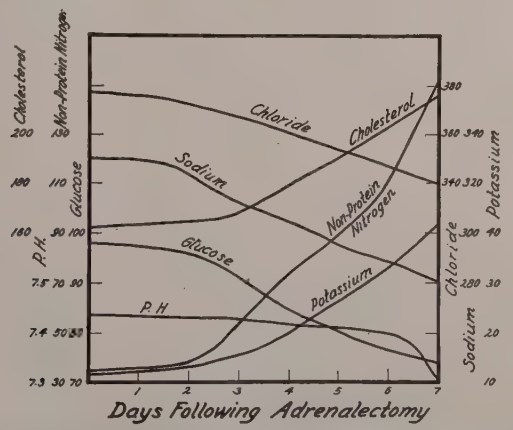

Fig. 354.—Changes in the blood chemistry in adrenal insufficiency. The curves represent composite records of results obtained on dogs adrenalectomized in stages. No therapy was given during the period of study and the animals died seven days following the removal of the second gland. With the exception of the pH, values are expressed in milligrams per 100 c.c. (ml.). (From Grollman: *The Adrenals*, Baltimore, 1936, The Williams and Wilkins Company.)

continues to diminish, partly because of the anorexia and partly because of dehydration. Accompanying the dehydration, and perhaps because of it, the plasma volume decreases and the red-blood-cell count goes up. The changes are indicated in Fig. 353. Similar increases are noted in the blood cholesterol and the blood potassium with even more marked increase in the nonprotein nitrogen,

which may reach values five or six times the normal. The sodium and the chloride content of the blood falls as commonly does also the blood sugar (Fig. 354).

The precise cause of death in adrenal deficiency has been much debated. Hartman[62] believes that the cause is a generalized interference with cellular metabolism. Britton[21] has laid special stress on disturbance of sugar metabolism as being fundamental, while Swingle[135] has claimed that the central feature is a shocklike inability of the organism to maintain the normal volume of circulating fluid. Considerable stress is laid by some authors on the rise in blood potassium and the resulting potassium-sodium imbalance that follows adrenal extirpation.[53] Restoring the balance by the administration of sodium chloride together with sodium citrate (to counteract the tendency to acidosis which develops) has an ameliorating influence in subjects with Addison's disease as well as in experimental adrenal deficiency. Kendall has reported that with no other treatment than administration of these salts two dogs have survived in complete health for a period of months without any cortical tissue whatever.

Cortical Extracts.—When it became apparent, early in the present century, that it is the cortex which is the vitally necessary part of the gland, many efforts were made to secure the cortical hormone in extracts sufficiently potent to prevent the syndrome of adrenal deficiency. Occasional claims of some degree of success were made but failed of satisfactory substantiation. As late as 1924 Sharpey-Schäfer[125] wrote: "There is no clear evidence that any kind of active . . . . substance is produced by the adrenal cortex." The first reported successes that attracted wide attention were those of Rogoff and Stewart[115] and of Hartman, MacArthur and Hartman[65] in 1927. Both reports were in the form of brief preliminary notes in which it was stated that extracts had been secured which significantly prolonged life in dogs or cats from which both adrenals had been removed. Stewart and Rogoff used saline solution and glycerin as extracting media and Hartman used a sodium chloride extract from which the proteins were removed by isoelectric precipitation. For the vital hormone Hartman proposed the name *cortin.* Subsequent work has shown that none of these methods possesses more than minimal efficacy but the two reports were very significant for the stimulus they afforded to further studies. The first investigators to report a method of preparing extracts sufficient to maintain indefinitely the lives of adrenalectomized animals were Swingle and Pfiffner.[136] This was in 1930. Two months later Hartman and Brownell[63] reported an equally successful method. At the present time several methods are available, each of which yields extract capable of prolonging indefinitely the lives of animals devoid of cortical tissue and of significantly ameliorating the symptoms of Addison's disease (Harrow and Sherwin[61]). Of these the process of Swingle and Pfiffner has been most widely used, but Grollman claims unusual simplicity for his method.

Although several crystalline products have been obtained from cortical tissue it cannot be said with certainty that any one represents the vital hormone. Cevitamic acid (vitamin C) which occurs in fairly high concentration in the adrenal cortex is apparently devoid of hormonal influence.

Whether the adrenal cortex forms more than one hormone and whether any available extract represents the entire potency of this structure are moot questions. Hartman[64] has reported that cortin does not support lactation, but that it is possible to derive another cortical extract, *cortilactin,* which does. Hoskins and Freeman[71] have found that a simple glycerin extract of adrenal cortex has

a significant influence in raising the blood pressure in a considerable proportion of human subjects, an effect not obtainable under comparable conditions from cortin or similar preparations. They believe that it represents a principle different from the so-called "vital" hormone. It may be this pressor principle, formed in excess, that gives rise to a condition of chronic hypertension which is occasionally seen in man and has not otherwise been accounted for (Barr[14]). It may be the absence of this principle from other types of cortical extracts that accounts for their relative inefficacy in sustaining the blood pressure of subjects with Addison's disease. Larrain, Roberts, and Kunde[80] have discovered that if minced cortical tissue is dialyzed against distilled water it continues for weeks to give off a powerful pressor substance which is not adrenalin. The production of this material is apparently due to enzymatic action, since it is promptly suspended when cyanide is added to the gland substance. Whether it represents a hormone or a chemical artifact is not known.

The availability of potent cortical extracts has made it possible, by subjecting animals to adrenalectomy and then partially supplying their hormonal need, to create a condition of *experimental chronic adrenal deficiency*—a condition that more or less closely simulates Addison's disease. The result is a general loss of vitality manifested especially by a lack of spontaneous activity and increasing malnutrition with almost complete loss of body fat. In young animals growth is retarded or suspended in accordance with the severity of the deficiency. Growth capacity can be restored by cortical extract, a fact that some investigators have utilized for the assay of extracts. The sex functions are depressed or obliterated; male animals become impotent and females remain in a state of permanent diestrus. Chronic deficiency renders the subjects less than normally resistant to environmental stresses and they succumb easily to intercurrent disease. Lesions are sluggish in healing. The animals are reported to be particularly susceptible to vitamin deficiency. By gradually decreasing the supply of extract the condition can be brought to a terminal stage closely resembling that of Addison's disease. A noteworthy exception, however, is that it has not been possible to reproduce with certainty the pigmentation that is characteristic of this disorder in man.

For the most part the *visceral changes* noted in animals dead of adrenal deficiency are simply those of "chronic passive congestion," a marked hyperemia of the visceral organs—stomach, intestines, liver, spleen, kidneys, pancreas, thymus, and hypophysis. Lesions of the gastric mucosa are characteristic; they include hemorrhage, superficial erosions, and true ulcers. Degenerative changes in the liver are common, a fact of interest in connection with the disturbance of carbohydrate metabolism characteristic of the disorder. Especially noteworthy are hypertrophic changes in the lymphatic system and in the pancreas. Despite the fact that cardiovascular weakness is a prominent symptom during life, the heart and blood vessels are found to be approximately normal. Altogether, postmortem studies have added little to our knowledge of the functional significance of the adrenals.

The relationship of the adrenals to the *respiratory metabolism,* despite a great deal of study, is not entirely clear. Immediately after adrenalectomy a mild fever associated with increased "basal metabolism" is frequently observed. Marine has laid stress upon this phenomenon as indicative of an intimate relationship between the adrenals and the thyroid, the hyperthermia being

ascribed to sudden escape of the thyroid from adrenal control. The increase, however, is soon succeeded by a substantial depression of the rate of oxygen consumption. In the terminal stages of adrenal insufficiency the rate may be less than half the normal value. A similar depression of the body temperature is seen.

FUNCTIONAL RELATIONSHIPS OF ADRENALS TO OTHER ENDOCRINE GLANDS

Adrenal-Pituitary Relationship.—Of recent years much stress has been laid on the controlling influence of the *anterior pituitary* upon the adrenal cortex. The relationship seems to be reciprocal. In dogs maintained on minimal doses of adrenal cortical hormone for periods of one hundred days and then allowed to die of adrenal insufficiency, Grollman and Firor[54] found changes in the pituitary similar to those reported in patients dying of Addison's disease. There was congestion of the gland and a marked decrease in the basophilic cells. Such animals develop a clinical picture essentially like that of hypophyseal cachexia. The physiological deficiencies manifested by such animals are not remedied by treatment with cortical hormone but are in some measure corrected by treatment with anterior pituitary extracts. Young animals suffering from early adrenal deficiency respond to cortical extract by an increase in the growth rate, but it is possible by long-continued subacute deficiency to set up a condition in which little growth response can be obtained. In such conditions the normal growth rate can be restored by the use of anterior pituitary extract. The importance of the pituitary-adrenal relationship is also shown by the fact that the depression in the reproductive system that occurs in chronic adrenal deficiency can be corrected more successfully by pituitary than by cortical extracts.

The Influence of the Adrenals Upon Pancreatic Diabetes.—An interglandular relationship demanding consideration is that between the adrenals and the *pancreas*. Long[85] has observed that experimental diabetes mellitus can be ameliorated by adrenalectomy. The effect is similar to that produced by hypophysectomy (see pages 765 and 767). Long's work was made possible by the availability of potent extracts of the adrenal cortex. These permitted the study of totally depancreatized and adrenalectomized cats over survival periods of several weeks. It was found, for example, that the average survival of adrenalectomized-depancreatized cats was nearly three times as long as that of cats in which only the pancreas had been removed. But the mere extension of the survival period is of far less significance than the fact that the double ablation prevents the rise in the excretion of glucose and nitrogen to the high levels characteristic of the pancreatectomized animal. Further, the typical ketonuria with acidosis fails to develop. Table CVII shows this and compares the results with those obtained in the hypophysectomized-depancreatized animal. Long has secured evidence that the effect of adrenalectomy on the course of pancreatic diabetes is not due to removal of the adrenal medulla. When this operation is performed in partially depancreatized rats the glycosuria temporarily disappears only to return to its initial level; if then total adrenalectomy is carried out, the glycosuria disappears permanently. It was also found that the innervation of the adrenals is not concerned, for cats with denervated glands rapidly succumb to the effects of pancreatectomy. It

can be concluded that the amelioration of diabetes mellitus by adrenalectomy is the result of removal of one or more hormones of adrenal cortical origin.

Relationship of the Adrenals to the Gonads.—That a relationship exists between the adrenals and the *sex organs* has been clearly recognized since Bulloch and Sequeira[26] described a condition now commonly known as the *adrenogenital syndrome.* A few years later Glynn[52] described at length the condition as it occurs in women and children. The salient fact is that hypertrophy of the adrenal cortex and precocious development of the sex organs occasionally take place coincidentally. In some instances mere accentuation of the sexual attributes is noted but usually in females there is also a more or less well-marked transformation toward the masculine type. The disorder occurs about five times as frequently in girls as in boys. In the juvenile form the onset is usually within the first two years of life. According to Grollman[53] the condition is marked by hyperplasia of the androgenic zone of the cortex and this leads to the appearance of such secondary male characteristics as increased

TABLE CVII

SURVIVAL AND THE EXCRETION DURING FASTING OF GLUCOSE, NITROGEN, AND ACETONE BY VARIOUS CATS (FROM LONG[85])

*Signifies Gm. or mg. per kg. per day.

muscular development, deepening of the voice, luxurious growth of hair (pubic and sometimes facial), hypertrophy of the vulvar structures, and enlargement of the clitoris to simulate a small penis. At times the ovaries and uterus share in the enlargement, but menstruation does not occur. The picture in boys is comparable; the secondary sex characteristics become accentuated, but the testes remain immature. The term "infant Hercules" is often applied to boys who have suffered this mishap. The condition differs from true precocious puberty that may result from tumors of the pineal or of the primary gonads in that it is only the secondary characteristics which are affected. Since the cortical involvement is frequently a malignant neoplasm that metastasizes freely it is important that surgical intervention be instituted early in the development of the syndrome. The surgeon, however, should examine both glands because occasionally that opposite the one affected is rudimentary or absent.

When the adrenogenital syndrome arises in adult women the condition is usually called *adrenal virilism.* It occurs most often either during the early years of adolescence or at the climacteric, but cases have been reported in the intermediate years. The picture is one of regression of the feminine secondary

sex attributes and of a transformation toward the masculine, similar to that described in the juvenile form. The vagina, mons veneris, labia, and mammae atrophy, and regressive changes in the ovaries have been described; menstruation ceases. The pubic hair pattern assumes the masculine form and excessive hair growth occurs, particularly on the face, chest, and thighs. The larynx also assumes masculine proportions. In the early stages of the disease marked adiposity of the upper half of the body is common. Later, cachexia and progressive asthenia occur. When only one of the two adrenals is involved, surgical treatment may be largely or entirely curative.

The condition of adrenal virilism is closely similar to, if not identical with, the *pituitary basophilism* described by Cushing. There is a rare type of neoplasm of the ovary, *arrhenoblastoma,* which also gives a similar clinical picture, a fact which suggests that certain accessory ovarian cells and those of the androgenic portion of the adrenal cortex are functionally identical. A characteristic case of arrhenoblastoma has recently been described by Baldwin and Gafford.[13]

Rarely, a condition, the converse of virilism, namely a transformation to the feminine type, occurs in males in association with tumors of the adrenal cortex. Such a case described by Lisser[84] was characterized especially by enlargement of the breasts and lactation. In one such case surgical removal of the adrenal tumor resulted in regression of the breasts and resumption of normal masculine sex functioning. Obviously, the occurrence of such instances, rare though they be, necessitates hesitancy in ascribing purely masculinizing potency to the adrenal cortex; the term *androgenic* tissue may have to be supplemented.

The relationships between the adrenals and the reproductive functions have been further discussed by Looney.[86]

There is a condition known as *pseudohermaphroditism* that has been somewhat plausibly ascribed to overactivity of the adrenal cortex during the prenatal stage of existence. In this condition the uterus and primary gonads are indubitably feminine but the external genitalia are largely of the masculine type. In some of the more recently reported cases hyperplastic changes in the adrenal cortex have been seen.

The *total biological significance* of the adrenal glands cannot at the present time be assayed. The medulla seemingly has an important function of aiding in adaptation to conditions that demand vigorous neuromuscular activity. In this it supplements sympathetic activity (see Chapter XVI). That the cortex has important functions may be assumed from its occurrence throughout the vertebrate group and from the fatal results of its destruction. The fact that it is proportionately very large during the prenatal period suggests that it may have an important part in the regulation of early growth and development. Its precise connection with reproduction has not yet been clearly elucidated, though its relationships with the pituitary and the gonads clearly indicate important regulatory functions. Its relationship to carbohydrate and fat metabolism and to the process of lactation demands further investigation. It seems probable that the cortex secretes more than a single hormone and that no extract that has hitherto been described represents the total potency of the structure.

CHAPTER LXXIII

THE HYPOPHYSIS OR PITUITARY GLAND

References to the pituitary as a distinct anatomical structure occur in medical writings as early as the time of Galen. Vesalius gave it the name "pituitaria" thus perpetuating a long-held misapprehension of its function, that of secreting a pharyngeal lubricant (*pituita*, mucus). This secretion was supposed to pass through the interstices of the cribriform plate of the ethmoid bone into the nasal cavity. After Conrad Schneider overthrew this idea in 1660 the gland came to be regarded as merely a vestigial organ.

Various aberrations of the growth processes now known to be due to pituitary abnormalities have long been recognized. Giants and dwarfs have engaged the folk imagination from time immemorial. The actual relationship of the pituitary to bodily overgrowth first came to be appreciated in connection with acromegaly, a modified type of gigantism. A case was reported by Verga in 1864 in which abnormality of the pituitary gland was recognized. Klebs thirty years later treated the subject of acromegaly in a monograph; the excessive size of the pituitary was emphasized, but the question whether the glandular enlargement was to be regarded as the cause or merely as a part of the bodily overgrowth was left undecided. To Pierre Marie (1886) is usually given the credit for having finally determined the causal relationship of the pituitary to acromegaly.

The reader is referred to textbooks of histology for a detailed description of the various components of the pituitary gland. It must suffice here to give a mere outline of the organ as it appears in the mammal. The reader should turn to page 189 for an outline of the major divisions and subdivisions of the hypophysis. These are also indicated in Fig. 355. Two main divisions are distinguished. The *neurohypophysis* is derived from the infundibular process of the diencephalon, while the three subdivisions of the *adenohypophysis* represent differentiations of Rathke's pouch of buccal ectoderm. The buccal derivatives are the pars distalis, pars intermedia and pars tuberalis. Usually the term *anterior lobe* refers only to the pars distalis. The term *posterior lobe* is sometimes used to describe all of the gland lying behind the intraglandular cleft (the residual lumen of Rathke's pouch) and thus includes the pars intermedia as well as the pars neuralis, but more commonly it refers to the neural portion alone. The position of the pars tuberalis varies somewhat in different species; it usually forms a collar around the upper part of the pituitary stalk and spreads to a greater or lesser extent over the ventral suface of the tuber cinereum. Its functions are not understood.

The parts of the pituitary possess different histological features. The pars nervosa is composed of neuroglia, unmyelinated nerve fibers and certain peculiar neuroglia-like cells which have been termed pituicytes (Bucy). The cells of the adenohypophysis are definitely of the secretory type. In the anterior lobe (pars distalis) two types of cells, the *chromophiles* and *chromophobes* can usually be recognized. On the basis of staining reactions the chromophilic cells are divisible into *acidophiles* and *basophiles*. The chromophobic cells may be mother structures for the two chromophilic elements. The cells of the pars intermedia are nongranular basophilic cells, but they differ from the basophilic elements of the anterior lobe. The intraglandular cleft tends to be filled by a colloid material which certain writers have supposed to be a secretory product of the pars intermedia. In some species, especially the primates, cells from this portion of the gland invade the pars neuralis. The pars tuberalis consists of cells arranged in acini which are sometimes filled with a colloid-like material. Histologically, the pars tuberalis differs from all other parts of the pituitary; the cells are usually faintly basophilic.

The pituitary gland of mammals receives its blood chiefly from a number of small arteries which arise from the circle of Willis and accompany the stalk. Wislocki and King[143] have recently shown that in the monkey the anterior lobe is supplied by afferent portal veins as well as by arteries and that the two unite to form the sinusoids which are characteristic of this portion of the gland. The efferent venous drainage of the pituitary as a whole is by veins which enter the cavernous sinus. According to Wislocki and King the portal system of veins originates in capillaries in the stalk. Previously Popa and Fielding[109] had claimed that in the human an extensive set of portal veins carries blood from the entire pituitary into the nervous tissue of the hypothalamus, but Wislocki and King were unable to find any evidence of this system in the monkey.

The nerve supply of the hypophysis has two origins. Sympathetic fibers from the superior cervical ganglia have been traced into the anterior lobe (Dandy), but up to the present no clear-cut function has been ascribed to them. Of apparently greater functional importance are the unmyelinated fibers which reach the gland from the hypothalamus by way of the pituitary stalk (see Chapter XVII). The histological evidence available shows quite clearly that they supply the pars nervosa and, to a less extent, the pars intermedia. The work of Ranson and his collaborators[113, 110] has shown that these fibers are active in connection with the elaboration of the antidiuretic hormone of the posterior lobe. Brooks[22] has secured evidence which demonstrates that in the rabbit ovulation depends on the activation of the anterior lobe by nerve fibers which course in the stalk.

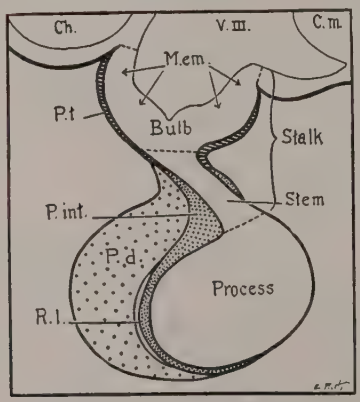

Fig. 355.—Diagram of the hypophysis of a monkey (*Macaca mulatta*) showing the subdivisions of the gland.

Bulb, infundibular "bulb" or "infundibulum" of Tilney; *Ch*, optic chiasma; *C. m.*, corpus mammillaria; *M. em.*, median eminence; *P. d.*, pars distalis (anterior lobe); *P. t.*, pars tuberalis (shaded); *P. int.*, pars intermedia (fine stippling); *Process*, infundibular process (neural lobe); *R. l.*, residual lumen (intraglandular cleft); *Stem*, infundibular stem; *Stalk*, neural stalk together with mantle of lobus glandularis constituting the hypophysial stalk; *V. III.*, third ventricle. (From Rioch and Wislocki in *The Hypothalamus*, A. Research Nerv. & Ment. Dis. Proc. 20: 3, 1940, Williams and Wilkins Company.)

The hypophysis appeared early in vertebrate evolution. In the lowest fishes it is represented by an open gland discharging directly into the pharynx. Also in the human embryo the gland has an early origin. By the fourth week of intra-uterine life the pharyngeal and neural components have already made contact. By the eighth month the blood supply of the gland has become rich and secreted material is being deposited in the cleft. In the ninth month the final cell types are determined. As to how early the gland begins to function in man little information is available, but in the pig embryo it yields a growth-promoting extract when the animal is at about half the birth-length. It is at this stage too that thyroxine can first be detected in the thyroid gland. In

amphibia it is possible to remove the pituitary at an early larval stage. The operation results in interference with development; the adrenals, the gonads and the thyroid fail to reach normal proportions and, in consequence, metamorphosis from the larval to the adult form fails to take place. It seems probable that the human pituitary plays a significant rôle in development from the early fetal months on. During pregnancy the hypophysis of the mother hypertrophies, a fact suggesting that the fetus obtains part of its growth hormone through the maternal circulation. The growth impulse, however derived, persists for a short time after birth even if the pituitary gland is removed. After this early period, however, the operation promptly and permanently renders growth impossible except as missing hormones are artificially supplied.

From the physiological point of view the hypophysis must be considered in relation to its various components. As sources of potent extracts the anterior and posterior lobes are distinctly different. There is also evidence that the pars intermedia subserves an independent function. The function of regulation of growth can be rather definitely ascribed to the acidophilic cells of the anterior lobe. The differential function of the basophils is less clearly known, but Zeckwer[147] has obtained some evidence suggesting that they produce hormones which regulate the thyroid, adrenal and sex glands. That an active extract can be secured from the neural lobe seems at first sight anomalous, for it is made up largely of neuroglia tissue and does not appear to contain definite glandular cells. Many investigators have concluded that its pharmacological activity is derived from cells of the pars intermedia or anterior lobe. There is, however, excellent evidence that the active substances (antidiuretic, pressor, and oxytocic) in question are actually produced by elements in the neurohypophysis. For example, they disappear from the gland when the neural lobe atrophies as a result of cutting the pituitary stalk, a procedure which does not cause atrophy of the pars intermedia and pars distalis.

A major difficulty in the elucidation of the functions of the pituitary is the intimate relation between the gland and the adjacent parts of the brain. Injuries to the hypothalamic area, whether produced experimentally, by accident, or by neoplastic invasion, have been shown to lead to such disturbances as obesity, polyuria and abnormalities of carbohydrate metabolism (see Chapter XVII). Similar disorders can be produced experimentally by injuries to the hypophysis. Experimentally it is extremely difficult to remove all of the gland without injuring the hypothalamus. In many animals the position of the pars tuberalis is such that at least some of it remains after the contents of the sella turcica have been completely removed. It is possible that this fact accounts for some of the discordant results which have been reported. Unfortunately scarcely anything is known of the functional properties of this portion of the gland. It has been suggested that the hypothalamus and the hypophysis constitute a functional system similar to that of the adrenal medulla and the sympathetic nervous system (see Chapter XVII).

THE NEURAL LOBE AND THE PARS INTERMEDIA

Knowledge of the functions of the posterior lobe, which consists of pars intermedia and neural lobe, has been difficult to secure. The classic first approach to experimental endocrine physiology, namely, study of the effects of extirpation of the structure in question, has yielded relatively little information regarding the

normal functions of the posterior lobe. Here a clean-cut surgical extirpation without significant injury to adjacent structures is most difficult—perhaps impossible. When an ablation has been confined very largely to the posterior lobe the one outstanding result is an increase in the amount of water ingested and excreted. This experimental polyuria with polydipsia is in every way similar to clinical cases of *diabetes insipidus* in many of which evidence of pituitary involvement is found. In both the experimental and the clinical forms of this disorder the polyuria can be controlled by administration of extracts of the posterior lobe of the pituitary. This fact has led to the belief that diabetes insipidus is due to a diminished output of an antidiuretic hormone from the posterior pituitary. Today the bulk of evidence favors this view. It also appears that the continued production of the antidiuretic substance depends upon the integrity of the innervation of the secretory cells by a group of fibers which arise in the hypothalamus, chiefly in the supraoptic nuclei. The cells which elaborate the antidiuretic hormone are found not only in the neural lobe but also in the pituitary stalk and even in the median eminence. Their distribution appears to differ in different species. Ranson and his collaborators[110] have shown that interruption of the fibers of the hypothalamico-hypophysial system (see page 192) leads to a permanent experimental diabetes insipidus with atrophy of the neural lobe. Richter,[111] working on rats, and Ingram and Fisher,[74] who used cats in their experiments, found that at least a part of the anterior lobe must be left to obtain a permanent polyuria after ablation of the neural lobe. The inference is that the pars distalis elaborates a diuretic hormone. It is a fact that complete hypophysectomies rarely produce permanent polyurias. It has been found that the disturbance in water balance does not develop if only a small fraction of the neurohypophysis is left intact.

The literature on the subject of the relation of the pituitary and the hypothalamus to water balance presents a most confusing picture. It has been frequently claimed that a hypothalamic injury is essential for the production of polyuria and even that such injury leads to a permanent polyuria after complete removal of the pituitary (Camus and Roussy; Bailey and Bremer). On the basis of the work of Ranson and his collaborators[43, 110] on cats and monkeys one may conclude that hypothalamic injuries are effective because they destroy the tonically active nerve supply of the posterior lobe, thus stopping the elaboration of the antidiuretic hormone. Richter's results suggest that the polyuria is dependent on the unantagonized action of a diuretic substance given off by the anterior lobe. Certain findings, however, appear to contradict these interpretations of the matter. It has been claimed that in the rabbit and monkey complete section of the stalk does not influence the urinary output in any permanent manner. It now seems reasonable to interpret these negative results as being due to the fact that unless the stalk section is very high it fails to disconnect the nerve supply of many of the cells which secrete the antidiuretic hormone. As indicated above, these may be distributed in the stalk and median eminence as well as in the neural lobe.

In connection with their classic studies on adrenal extracts in 1894 Oliver and Schäfer[106] discovered that the injection of pituitary extract causes a marked rise in blood pressure. Subsequent researches showed that it was the posterior lobe that contributed this property (Howell, 1898). Supplementary to this observation is Cushing's report[32] that localized tumor growth which compresses the pituitary stalk in man and thus presumably stops the discharge of posterior-lobe secretion may result in low blood pressure. The case is cited of a twenty-three-year-old victim of such a growth in whom the systolic pressure was only 60 mm. Hg.

In 1909 Dale[34] reported the discovery that injection of posterior-lobe extract causes a marked contraction of the uterus—as it does of smooth muscle generally. Abel and his associates[1] have devoted much study to the chemistry and pharmacology of posterior lobe extracts. They have succeeded in deriving a tartrate so potent as to cause marked contraction of uterine muscle when applied in concentration of 1:15,000,000,000 or less than one grain in a thousand tons of fluid. This substance possesses pressor, oxytocic (uterus-stimulating) and antidiuretic properties. Kamm and his associates[76] have separated from postpituitary extracts two fractions, "*pitressin*" and "*pitocin,*" in a highly purified state. In experimental animals pitressin has a marked stimulatory influence on blood pressure and respiration, and it sharply checks the secretion of urine. It has also a certain melanophore-expanding activity, but this according to Geiling[49] decreases with purification and is due to a separate principle elaborated by the cells of the pars intermedia. Pitocin has mainly an oxytocic activity. Both pitocin and pitressin cause hyperglycemia and counteract the effects of insulin.

In the human subject therapeutic injections of either total posterior lobe extract or of pitressin cause a marked pallor of the skin but little or no significant rise of blood pressure. There is a brief fall in pulse rate, in oxygen consumption and heart-output which is followed by a more prolonged rise. The decreased cardiac output results in an accumulation of catabolites associated with the decreased oxygen consumption which is followed by a compensatory secondary increase. In experiments in which cardiac effects are eliminated, larger doses of the extract produce a sharp rise of blood pressure but on repetition of the injections the effect is soon lost.

In the earlier experiments with posterior lobe extracts it was noted that the immediate effect in experimental animals was an increase of urine flow. Accordingly, in the older literature the extracts figured as "diuretic." Subsequent work, however, has shown that therapeutic doses of either the post-pituitary extract or of pitressin have a marked antidiuretic effect. As already mentioned, this property is of use clinically in the treatment of diabetes insipidus, in which condition a troublesome urinary output that may reach ten or more liters per day can readily be held within approximately normal limits by injections once or twice daily. The action is, at least mainly, on the kidney itself and is probably due to an increased reabsorption of water by tubule cells. McQuarrie[93] has recently reported several cases in which pitressin injections caused temporary water-retention which was followed by a marked diuresis that more than compensated for the initial antidiuretic effect. He was thus able to bring about marked reduction in an existing edema. He surmised that this secondary reaction might be due to induced secretion of an anterior-lobe diuretic principle.

The oxytocic effects of post-pituitary extracts are modified by various factors such as species, phase of the sex cycle, pregnancy itself, and the stage of pregnancy. During the early phases of pregnancy in human cases the uterus fails to react to pitocin but does respond to small doses of pitressin. Later in gestation it becomes reactive to pitocin and the parturient uterus is highly reactive. In the puerperium the reaction is again lost. The principal clinical use of posterior lobe extract is in the stimulation of uterine contractions during childbirth, and more especially, to bring about such contraction as will check post-

partum hemorrhage or bring to completion an arrested abortion. It is of some utility in the induction of labor but must be used with caution. It is effective when administered intranasally and this route is often advisable, permitting, as it does, the cautious building up of the dosage to the effective point. Overdosage may be disastrous. As a smooth-muscle stimulant the drug is also occasionally of practical use in overcoming atony of the intestines or bladder.

From the foregoing evidence it may be rather plausibly surmised that the posterior lobe of the pituitary has important physiologic functions in the control of the circulation and of smooth-muscle tonus generally, in the process of parturition, in water metabolism, and possibly in fat metabolism. It must be emphasized, however, that the various active principles do not necessarily represent true hormones—they may be chemical artifacts—and that their existence in the cerebrospinal fluid, into which it is commonly postulated that they are discharged, has not been satisfactorily proved. The paucity of evidence of physiological disturbances following destruction of the posterior lobe reenforces such doubt as one may entertain. If the pharmacological evidence is interpreted as indicative of the existence of hormone functions, it must be assumed that the body has at its command effective compensatory mechanisms that can be brought into play when the hormone secretion is interfered with.

Zondek[144] is a proponent of the view that the pars intermedia secretes a hormone which he calls "*intermedin.*" This substance is commonly found in extracts of the posterior lobe. It is notable chiefly for its effect in bringing about expansion of the melanophores in amphibia and certain fish. This reaction has been used in the quantitative assay of the material. Intermedin has not as yet been used at all extensively in clinical practice but such evidence as is available indicates that it is of use in the treatment of diabetes insipidus. It is said to differ in its action from pitressin in that it checks only water output whereas pitressin reduces both the fluid and the sodium-chloride excretion. The manner of its action is not known.

THE PARS DISTALIS OR ANTERIOR LOBE

Control of Growth.—Studies of the clinical manifestations associated with structural abnormalities of the pituitary have thrown considerable light upon the functions of the anterior lobe. Previous mention was made of the influence upon body structure of enlargement of this portion of the hypophysis. When the glandular overactivity antedates puberty, the whole body shares in the exuberant growth, and *gigantism* results. When it takes place after puberty, increase in the length of long bones is no longer possible, but other structures not thus circumscribed show generalized hypertrophy. Thus arises splanchnomegaly and distorting overgrowth of such structures as the inferior maxilla, the nose, the ears, the glabellar prominences and the hands and feet. At times the hebetic closing of the proliferative zones of the long bones intervenes in the overgrowth process with the result that what began as gigantism is completed as *acromegaly*.

Folk lore recounts the occurrence of very large giants but seldom does the height authentically much exceed eight feet. A few of the tallest giants on record are indicated in Table CVIII.

TABLE CVIII

(AFTER SCHERESCHEWSKY[122])

GIANT	AUTHOR REPORTING	HEIGHT
Kayanus		9.2 ft.
Winkelmeyer	Virchow	9.0 ft.
Krav	Kiari	8.9 ft.
Konstantin	Dufreny	8.4 ft.
Scotchman	Freulich	8.4 ft.
Austrian	Topiner	8.3 ft.

Rarely in gigantism and acromegaly the anterior lobe is found to be of approximately normal size but in such cases relative overdevelopment of the acidophilic cells is commonly evident. The weight of available evidence indicates that it is from these cells that the growth-promoting *(somatotropic)* hormone is derived.

A. *B.*

Fig. 356.—*A*, the appearance before the onset of acromegalic symptoms; *B*, the appearance after seventeen years of the disease. (After Campbell Geddes.)

Lee[81] and others have shown that extirpation of the anterior lobe results in a profound alteration of the metabolic processes. The work suggests that the growth hormone has a relationship to protein metabolism somewhat comparable with the relationship of insulin to carbohydrate metabolism. In the absence of the growth factor the assimilation and storage of protein are interfered with. The defect can be compensated by the administration of a suitably prepared anterior lobe extract. The hormone in this case is either a globulin or is of such nature that it appears with the globulin fraction in purified extracts. Riddle[114] has raised the question, however, whether the so-called "growth hormone" represents a single entity or whether it is a composite of other fractions that have individually different functions than the promotion of growth. At any rate no one has yet succeeded in producing a growth fraction that is entirely free of effects ascribable to other fractions. The inherent complexities of protein chemistry render the problem difficult of solution.

The fact that the growth fraction is no more abundant in the anterior lobes of calves than of adult cattle suggests that the somatotropic hormone functions throughout life, but of its functions in adult years we have little knowledge beyond the suggestion from the work of Lee that it may continue to serve as a regulator of protein metabolism.

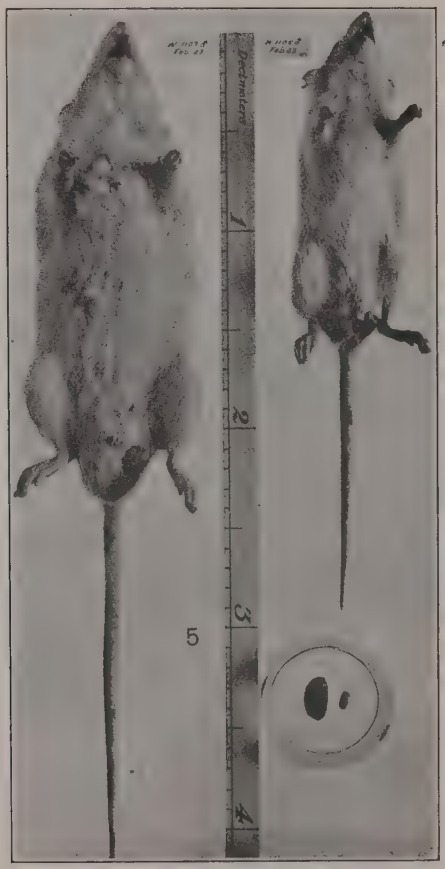

Fig. 357.—Photograph of a hypophysectomized rat and its litter mate control. The hypophysectomy was done at the age of thirty-six days; weight, 96 Gm. The photograph was taken eighty-nine days later. A testis removed from each animal at this time is also shown. (After P. E. Smith.)

Failure of development of the anterior lobe results in the condition known as *dwarfism*. The first major surgical contribution to the physiology of the pituitary was the proof by Aschner and by Cushing that experimental dwarfism can readily be produced by destruction of the anterior lobe. The type of human dwarfism due to deficient production of the somatotropic hormone has been designated by Erdheim as *nanosomia pituitaria*. Several other types

are known of which the most interesting, from an endocrine viewpoint, is that due to hypothyroidism. Evans[40] believes it probable that all forms of dwarfism are directly due to inadequate pituitary function but that this inadequacy may be brought about by several antecedent factors. Experimental dwarfism is frequently associated with obesity, but this is usually ascribed to injury of the hypothalamus incident to the operation. The final proof that the dwarfism is due to deprivation of growth hormone rather than merely injury of trophic structures in the nervous system has been afforded by Smith[132] and others who have been able to restore the growth impulse either by the implantation of anterior lobe grafts or by the injection of anterior lobe extract (Figs. 358 and 359). The latter is now being used to some extent clinically in the treatment of dwarfism, but so far with only moderate success (Shelton[128]).

Fig. 358.—Photographs of two female rats about four hundred days old. The rat on the right received daily intraperitoneal injections of anterior pituitary extract. Its litter mate sister on the left was untreated. (After Evans.)

The classification of human dwarfism at the present time is somewhat unsatisfactory. The difficulty is due in part to the fact that the defective growth may or may not be associated with failure of sexual development or function. Some dwarfs have normal adult proportions but more often those of childhood are retained, the upper length of the body exceeding the lower. In some cases of dwarfism a peculiar senile manifestation (*progeria*) is seen. Thus the individual may become senescent at 25 and suffer an early death.

Another clinical manifestation of pituitary deficiency in which the somatotropic factor is involved is a peculiar cachectic condition reported by Simmonds in 1914. *Simmonds' disease* is marked by a rapidly wasting state which is found at autopsy to be associated with destruction or sclerosis of the pituitary. In this case all parts of the gland seemed to be involved. According to Evans, Simmonds' cachexia is not due primarily to deficiency of growth hormone because when the condition is set up experimentally by pituitary destruction in animals, it cannot be corrected with purified growth extract but can be relieved by more crude preparations. The course of Simmonds' disease may be rapidly

progressive to a fatal issue or death may be postponed for years. The patient ages prematurely as is indicated by such manifestations as atrophy of the skin and loss of hair. The emaciation affects the body tissues generally and gives rise to progressively increasing weakness and fatigability. Lack of appetite is a common and stubborn symptom. Increased thirst and a voluminous urine output are frequently seen in the earlier phases of the disorder, but later tend spontaneously to be corrected. The oxygen-consumption rate falls well below normal and a moderate decrease in the number of erythrocytes occurs. Often carbohydrate metabolism is disturbed. The genital organs frequently show atrophy; depression of the sex functions is an invariable and usually an early symptom. These clinical observations have obvious connotations regarding the physiology of the pituitary.

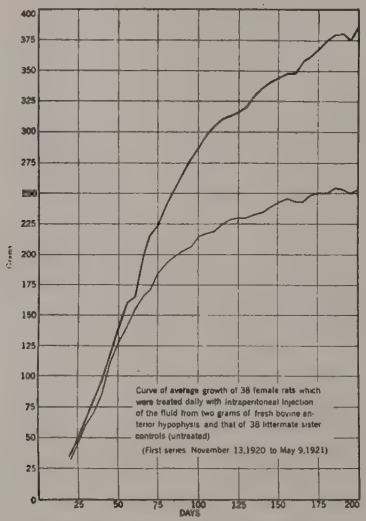

Fig. 359.—Curve of average growth of 38 female rats which were treated daily with intraperitoneal injections of anterior lobe extract; and that of 38 litter mate sister controls (untreated). (After Evans.)

The extent to which functional deficiency aside from Simmonds' disease may arise in later years of life is not known. Presumably the gland shares with other organs of the body a liability to such failure from the operation of fatigue, malnutrition, infection and what not. So complex are the functions now ascribable to pituitary secretions that the clinical manifestations of deficiency of the gland would presumably be multiform. Among the symptoms that have been vaguely ascribed to such pituitary depression are lowered oxygen consumption, malnutrition, weakness, generalized hypometabolism, eosinophilia, augmented uric acid titre of the blood, depression in the sex field and changes of disposition.

Gonadotropic Effects.—The first experimental evidence indicating a relation between the pituitary and the reproductive system was obtained by Crowe, Cushing and Homans in 1910. In the course of a study of the effects of

complete and partial hypophysectomies they found that when adult dogs were deprived of all but a fragment of the anterior lobe reversive sexual changes set in; the females failed to come in heat and the males exhibited no signs of sexual activity. When similar operations were performed on puppies a persistence of sexual infantilism resulted. Two years later Aschner also found that hypophysectomy causes an atrophy of the reproductive system. Since that time these results have been abundantly confirmed. The precise nature and origin of this hypophysial influence were not clearly shown until 1926 when it was independently discovered by P. E. Smith[132] and by Zondek and Aschheim[145] that implants of anterior lobe substance into immature rats and mice would bring about precocious sexual maturity within a period of about four days. In this way

Fig. 360.—Simmonds' disease in a woman aged fifty-three years. (Silver: Arch. Int. Med. 51: 175, 1933.)

it was conclusively shown that the anterior lobe maintains the activity of the gonads and through the internal secretions of these organs influences the other parts of the reproductive system.

The literature on this topic has already become highly complex. It has been authoritatively reviewed by Smith.[131] In the case of the female the elementary facts are that along with the typical growth of follicles, ovulation, and the formation of corpora lutea, there occurs as a result of implanting anterior lobe also a lutein-transformation of the walls of many ovum-containing follicles. The weight of the evidence at the present time is to the effect that two hormones are involved. One has been called the "follicle-stimulating hormone" (F. S. H.) and the other the "luteinizing hormone" (L. H.). Both are referred to as *"gonadotropic"* principles.

As regards the follicle-stimulator, the term is rather ill-chosen in that the male gonad is also influenced. In both sexes it is the germ cells proper that are affected, hence Smith proposes that it be designated as the *gametokinetic* hormone. The luteinizer, on the other hand, appears to act predominantly on the connective-tissue derivatives, the theca cells of the ovaries and the interstitial cells of the testes. In addition to their appearance in anterior-pituitary extracts, gonadotropic substances have been discovered in human blood and urine during pregnancy, after ovariectomy and at the menopause, in certain tumors of the reproductive organs, and, in smaller amounts, in the blood and urine of men and women during the normal reproductive period. A gonadotropic substance can be separated in relatively large amounts from the blood serum of pregnant mares and in small amounts from the blood of some other animals after castration. Some of these gonadotropic principles are derived from the anterior pituitary and some from the chorionic tissues of the placenta. A still different source is a peculiar tumor of the female, arrhenoblastoma, which

Fig. 361.—*Above:* Ovaries of litter mate control rat; *below:* ovaries of rat after twelve implantations of fresh rat pituitary gland. (After Collip.)

causes a marked masculinizing effect. The interrelation among, and the physiologic significance of, these various gonadotropic factors present difficult problems that are as yet only partly solved.

Several methods of fractionating anterior lobe extracts for gonadotropic factors are available. Hisaw and Fevold,[66] among others, have devoted special attention to separating the follicle-stimulating and the luteinizing principles. A fraction has been secured by the use of which pure follicular growth can be obtained in hypophysectomized rats, in young rabbits and, with limited treatment, in immature rats. In the latter form, however, corpus luteum formation is set up after several days treatment—a result that is ascribed to secretion of luteinizer from the animal's own hypophysis. In immature monkeys both the pituitary "F. S. H." and extract of urine of castrated animals give pure follicular growth. It is believed that these latter two substances are identical. Shedlovsky and his collaborators[126] have isolated the luteinizing factor in apparently pure form. It has the properties of a globulin. Its molec-

ular weight is about 90,000 and its isoelectric point pH 7.45. It was found to be a necessary adjunct to pure follicle-stimulator in the production of estrus in young hypophysectomized rats.

The action of castrate-urine "F. S. H." in hypophysectomized males is of special interest. The seminiferous epithelium of their atrophied testes shows a marked response, spermatids and even spermatozoa being produced, with little or no change in the interstitial tissue. Conversely, there can be obtained from pregnancy urine a fraction, possibly of pituitary origin, which produces not only luteinization in females but extensive hypertrophy of the interstitial tissues in males. Overactivity of the interstitial tissues is commonly associated with marked development of such secondary sex structures as the prostate and seminal vesicles.

Fig. 362.—Photographs showing the effects of the urinary gonadotropic substances on the ovary of hypophysectomized immature rats. *5* is the ovary of an untreated animal twenty days after hypophysectomy. *6* is from another immature rat twenty-five days after hypophysectomy; during the ten days preceding removal of the ovary the animal had received injections of an extract of human pregnancy urine (chiefly luteinizing substance). Note formation of luteinlike cells and absence of follicular growth. *7* is the ovary of an immature rat twenty days after hypophysectomy. The animal had received for five days an extract of urine from a castrate woman (follicle-stimulating substance). Note formation of many normal follicles with but slight indication of luteinization. (From Smith and Engle: J. Pediatrics, 5: 163, 1934.)

These topics will be further discussed in a subsequent section dealing with the physiology of reproduction.

The Lactogenic Factor.—Among other effects of anterior lobe pituitary deficiency is inability of a mother to secrete milk. Several investigators have obtained pituitary extracts which stimulate lactation. Riddle[113] succeeded in isolating the lactogenic factor in a degree of purity sufficient to permit a demonstration of its distinctiveness from the growth and gonad-

stimulating factors. He has called it, "*prolactin.*" Turner[138] who has also done important work on the subject, prefers to call it "*galactin.*" All the successful methods of preparing this fraction involve extraction of anterior-lobe tissue, precipitation in an aqueous medium by adjusting the pH to the isoelectric point and repeated washing of the precipitate. Salt-free preparations at a pH of 8.0 withstand boiling for an hour with little loss of potency. The active substance is completely destroyed by tryptic digestion—a fact which suggests that it, like other anterior pituitary hormones, is of a protein nature. There are four known responses to the administration of prolactin. These are setting up of lactation in mammals, growth of the crop gland in pigeons, initiation of broodiness in fowl, and marked diminution in the size of the active gonads of adult pigeons or fowl. The hormone apparently has no influence upon the growth or development of the mammary gland but serves only to set it into secretory activity after it has previously been prepared by the action of the ovarian hormones. A plausible theory is that during pregnancy mammary gland maturation is brought about by these hormones, which are especially active at that time, but that the action of the lactogenic factor is suppressed by ovarian or placental hormones that are known to be produced in large amounts during this period. At parturition the production of the suppressing factor ceases, thus liberating the secretion of the prolactin from the pituitary, whereupon the breasts begin active functioning. This theory is supported by the fact that treatment of male animals with ovarian hormones may bring about development and hypertrophy of the mammary glands after which the administration of prolactin leads to milk secretion.

Prolactin has also a marked influence upon certain instinctual reactions. Wiesner and Sheard[142] were able to bring about a marked development of the maternal instincts in virgin rats by the use of crude anterior pituitary extract. Riddle has extended their observations, using a purified preparation. Under its influence the rat develops a strong propensity to "mother" not only infant rats but also mice or squabs. She builds elaborate nests for them and hovers about them with all the solicitude of a veritable mother. The induction of broodiness and clucking in fowl presumably represents another manifestation of the same influence.

Prolactin has as yet been little used clinically, but Kurzrok[79] has treated with this substance a group of women in whom lactation had remained inadequate up to the sixth day after the birth of their infants. In most cases the milk production was significantly increased. In several women whose secretion was apparently normal prolactin produced no detectable effect.

The Thyreotropic Factor.—That a relationship between the hypophysis and the *thyroid* exists has long been known. A half century ago Rogowitsch[116] noted an enlargement of the pituitaries of dogs and rabbits following thyroidectomy. The observation has often been confirmed. Conversely, destruction of the pituitary has been shown by several observers to result in atrophy or failure of development of the thyroid. In tadpoles this atrophy prevents metamorphosis into the adult form but the ability can be restored by pituitary implants. In the rat, as shown by Smith,[130] hypophysectomy not only causes atrophy of the thyroid gland as shown by histologic observations, but also reduces the oxygen consumption rate as much as 35 per cent—the same amount as that produced by thyroidectomy. In man a similar reduction in the metabolic

rate has been shown to characterize Simmonds' disease of which thyroid atrophy is also characteristic. Conversely, thyroid hypertrophy can readily be set up by the administration of suitable anterior lobe extracts. The evidence strongly supports the belief that this latter effect is due to the action of a distinct principle, the *thyreotropic* hormone. Collip[30] and others have obtained a thyreotropic principle nearly or quite free from growth or sex-promoting activity. Friedgood[45] has pointed out the close resemblance between the condition produced by administration of thyreotropic hormone and that of exophthalmic goiter in man. The action of the thyreotropic hormone seems to be of limited duration, the hypertrophic effect in the thyroid with its accompanying elevation of the basal metabolic rate being followed by thyroid regression and fall of the rate even below normal. This latter effect may, however, be due to contaminating material in the extract rather than to the hormone itself. These observations obviously suggest that clinical hypothyroidism (myxedema) can arise not only from primary thyroid disease but as a secondary reaction to disorder of the pituitary.

The Adrenotropic Factor.—Almost as marked as the thyroid atrophy following pituitary extirpation is regression of the adrenal cortex. This regression can likewise be overcome by the administration of pituitary implants. In acromegaly and other clinical conditions associated with overactivity of the hypophysis hypertrophy of the adrenal cortex is of frequent occurrence. Presumably such observations indicate the existence of another anterior pituitary function; namely, that of secreting *adrenotropic* hormone. The separation of a fraction having a purely adrenotropic effect has been difficult, but Collip[29] has obtained a preparation which can be given in dosage adequate to cause marked adrenal hypertrophy without producing detectable influence on the thyroid.

Further evidence of a functional relationship between the hypophysis and the adrenals is seen in the condition of "pituitary basophilic adenoma" described by Cushing.[33] In this disorder a series of bodily changes arise that closely resemble, if they are not identical with, those of an "adreno-genital syndrome" which sometimes follows overactivity of the adrenal cortex. This topic has been discussed in the chapter dealing with the adrenals.

It is at least theoretically possible that Addison's disease, which is immediately due to destruction of the adrenal cortex, may actually have its initial cause in failure of the adrenotropic secretion of the pituitary. Supporting this possibility are two cases of that disorder mentioned by Collip in whom marked improvement occurred following the use of adrenotropic extract.

The Parathyreotropic Factor.—Clinical evidence for an interrelationship between the pituitary and the parathyroid glands has been reported by several observers. The association of parathyroid adenomas with tumors of the hypophysis is suggestive of such a relationship. It is claimed, too, that the urine of patients having hyperplasia of the parathyroids can be used to produce experimental hyperplasia in the same glands of rabbits. Riddle, however, has noted that similar effects can be brought about with prolactin and suggests that the so-called *parathyreotropic* hormone is no other than the lactation-producing principle.

Influence on Carbohydrate and Fat Metabolism.—What was already recognized as a highly complex situation—the endocrinology of the pituitary—was

rendered still more complicated when Houssay[72] in 1930-1931 reported the remarkable observation that removal of the hypophysis strikingly lessens the manifestations of diabetes in pancreatectomized animals. This procedure would seem to amount to superimposing the condition of Simmonds' disease upon that of diabetes. While neither disorder actually cures the other, the symptoms of each in considerable measure cancel those of the other and thus temporarily conserve the health of the experimental animal. In the dog the period of survival after the double operation may extend to six or nine months. That a relationship exists between the anterior pituitary and carbohydrate metabolism had previously been surmised from the frequent observation of glycosuria and hyperglycemia or even of frank diabetes in acromegaly, but the primacy of the association had not been appreciated.

The blood sugar of the "Houssay dog" is notably labile. During fasting it may fall below 100 mg. per cent and after feeding may rise above 300 mg. The animal becomes a sensitive test object for either pituitary extract or insulin: the diabetogenic influence of the pituitary factor is enhanced in the absence of insulin and the hypoglycemic effect of insulin in the absence of the anterior pituitary secretion. It seems obvious now, therefore, that the clinical disorder, "hyperinsulinism," which Harris[60] ascribed merely to overactivity of the islands of Langerhans will have to be reconsidered; it may actually arise as well from anterior pituitary deficiency as from a disorder of the insulinogenic function.

Collip[30] who has reviewed the cogent literature is inclined to ascribe the relationship between the anterior hypophysis and diabetes to the secretion of two pituitary principles, one, "*blood-sugar raising*" (it might be designated, "B. S. R.") and the other, "*ketogenic.*" The B. S. R. principle is intimately associated with the somatotropic principle and may be identical with it; at any rate Collip's most highly purified "growth extract" has the property of increasing the blood sugar. This effect of the B. S. R. is obtainable in thyroidectomized animals. It is not found in the posterior lobe and is neither pitressin nor oxytocin. The B. S. R., according to the Houssay school, is soluble in water and in 60 per cent alcohol; it is insoluble in absolute alcohol, ether, acetone, benzene and chloroform. It is thermolabile and does not pass through ultrafilters. It is readily adsorbable on kaolin, by virtue of which property it is easily recoverable from normal human urine. Large quantities can be obtained from diabetic urine. When injected parenterally, it raises the blood sugar only after a considerable latency, but if it is introduced into the cerebrospinal fluid, the reaction is very prompt. Lucke[87] believes, therefore, that its action is primarily upon the central nervous system—perhaps upon a hypothalamic center.

From alkaline extracts of anterior pituitary substance is derivable a fraction that has a marked influence upon fat metabolism. Under its influence the ketone bodies in the blood are substantially increased. It has been designated the "Fettstoffwechselhormon" or "orophysin" by Continental investigators but in the American literature it is usually called the *ketogenic factor.* Unlike the B. S. R. it is closely associated with the thyreotropic factor, but it is effective in thyroidectomized rats (Funk[48]). According to Magistris,[94] the ketogenic factor can be obtained from pituitary glands that have been stored in acetone. The powdered gland substance is extracted with wa-

ter. It is ultrafilterable and dialyzable. It is insoluble in absolute alcohol, ether or chloroform, but is soluble in dilute alcohol and water. Again, unlike the B. S. R. fraction, it is not adsorbable by kaolin though it is by silica gel. It may be obtained from the euglobulin fraction of blood serum or, according to Funk,[46] by shaking human urine with benzoic acid and purification of the precipitate thus formed. The ketogenic principle is reported to increase the specific dynamic action of protein.

In clinical diabetes mellitus, both the carbohydrate metabolism and the fat metabolism are profoundly disturbed. The trend of recent endocrine research is to indicate that the two aspects of the disease are intimately bound up with the B. S. R. and the ketogenic influences of the anterior lobe of the pituitary gland. It seems probable that the "diabetogenic principle" which is frequently alluded to in present-day literature actually represents a composite of these two factors.

Emphasis is due upon the fact that the foregoing discussion of pituitary physiology amounts to no more than an outline sketch which may serve as a skeleton for the organization of the complex mass of details with which anyone reading further into the subject will be confronted. Whether all the functions that are now ascribable to the pituitary represent the operation of separate individual hormones is doubtful. The possibility of mere mathematical permutations should be kept in mind. It is theoretically possible to derive from four factors sixteen characteristic combinations. Thus no more than four or five hormone entities need necessarily be postulated to account for the multiplex influences that the pituitary gland has been shown to mediate. Too, there is the possibility that the gland may secrete only a small number of mother substances from which the reacting tissues may derive this or that final active product in accordance with local needs or conditions. In any case the mere derivation of characteristic active bodies from glandular substance by no means assures their hormone status; they may be merely chemical artifacts.

Despite the assiduity with which researches on pituitary physiology have been prosecuted much that is fundamental remains yet to be discovered. The relationships that have been already disclosed are complex and stand in large measure in need of further resolution into their elements. In such studies it is important to realize that the conditions in the living tissues that determine the reactivity to a given hormone may be quite as important as the properties of the hormone itself. These reaction factors must be rigorously controlled if puzzling discrepancies of data are to be avoided. It now seems sufficiently evident that either directly or through their influence on the various endocrine glands and the nervous system the pituitary hormones have important regulatory influences upon most or all of the vital functions. A large problem, and one toward the solution of which only a beginning has been made, is the translation of pituitary physiology and pathology into terms of clinical symptomatology. For a further account of more recent developments in pituitary physiology Evans' review[41] may be consulted.

CHAPTER LXXIV

THE TESTIS

As has been recognized for centuries, the male sex glands are the primary source of the various qualities, physiological and psychological, that are connoted by the term, *virility*. Castration has been widely practiced both in human subjects and in farm animals, and the chief effects of that operation are matters of common knowledge. The testes, like the ovaries, have to be considered in their relationship both to sex and to reproduction.

Sex has been defined as "the sum of the peculiarities and functions that distinguish a male from a female organism." Some of these peculiarities have to do only indirectly with reproduction. The testis produces not only fertilizing elements, the spermatozoa, but also one or more hormones that have to do with the many physiological and psychological adaptations by which reproduction is brought about. In many of the lower forms of life reproduction is carried on by processes that are not sexual. The process of sexual reproduction is foreshadowed in that of conjugation in which the parent organisms fuse as a whole and subsequently divide to constitute the offspring. Early in the evolution of the higher forms the *gametogenic* tissues were set aside from the remainder of the body to be incorporated in the gonads.

Ordinarily there is a rather sharp demarcation between males and females but both testes and ovaries may occur in the same individual; in some species males and females are scarcely distinguishable. In the case of certain animals, for example the fowl, the same individual may successively possess the gonad tissue and the functions of the female and the male. In the human species true *hermaphroditism* sometimes occurs and normally each sex has in rudimentary form the reproductive structures and impulses of the other. In addition to the reproductive organs, proper, there are a variety of *secondary sexual characteristics* such as the horns of the stag, the mane of the lion, and color among birds. The distribution of hair in man is a typical example of a secondary sexual characteristic.

The segregation of the sex cells in different individuals has necessitated a variety of mechanisms and reactions for bringing the germinal elements together. The structure of the respective reproductive organs is an obvious case in point. The prostate of the male appears to have the primary function of protecting the viability of the spermatozoa and the seminal vesicles share in this function as well as to add bulk to the ejaculate. The utility of accessory structures of the female that secrete lubricating fluids is clear. The same is true of the orgastic reflexes of the male. The function of the female orgasm is not certainly established but a plausible surmise is that it serves to aspirate the ejaculate. Also, it may stimulate ovulation.

In addition to the anatomical and physiological differences between males and females there have arisen also distinctive sexual instincts. These control the behavior of the individuals in their reciprocal relationships, such as courting or estrus and mating, and they initiate such activities as nest building and

feeding of the young. In many animals the sexual instincts are operative only during the breeding season. Various secondary sex characteristics are exaggerated during the breeding season and wane with its passing. In the higher forms such periodical changes in the secondary sex characteristics are directly under the control of the gonads.

In most mammals the testes emerge from their initial intra-abdominal position into an extension of the body cavity, the scrotal sac. Occasionally, in man, they are retained within the body cavity to give rise to the condition known as *cryptorchidism*. The sex cells in the cryptorchid testis remain at an infantile stage of development, hence the subjects are always sterile. They often possess, however, their full complement of virile instincts and normal secondary sex characters. This fact establishes the high probability that at least the chief hormone function of the testis is mediated, not by the gametogenic tissue but by the interstitial cells of Leydig, which can develop in an approximately normal way even though the testis fails to migrate. The chief factor that prevents the development of the gametogenic tissue in the cryptorchid testis seems to be the relatively high temperature to which it is subjected. Sand[121] and others have shown that males can be easily sterilized by subjecting the gonads to elevated temperature of a degree otherwise harmless. In some animals, for example the rat, optimal temperature conditions are maintained by extruding or withdrawing the testes through the patent inguinal canal.

While there is no question that the changes characteristic of puberty are dependent upon gonad factors, there is some question as to the part played by the testes in the earlier years. Despite the fact that males and females are characterized from time of fertilization by a difference in the chromosome complex of the somatic cells the human infant is largely neutral both somatically and instinctually. As growth proceeds, however, a certain amount of differentiation occurs in the bodily form and perhaps in the disposition, though the latter may be due largely or entirely to social conditioning. With the onset of puberty the dimorphism becomes marked. That the gonads may have a significant influence even during intra-uterine life is suggested by the occurrence of *free-martins* in cattle. A cow may give birth to twin calves of opposite sex, each of which is normal. But occasionally the placentas to which the twins are attached become fused so that the blood streams of the two intermingle. In such cases the female shows considerable transformation toward the masculine form and remains sterile throughout life. This effect is plausibly to be ascribed to a masculinizing influence derived from the testes of the brother.

Castration of domesticated animals is a widely practiced farm procedure. The results of the operation are evident in the contrast between the docile ox and the aggressive bull. When the operation is practiced at the prepuberal stage the results are quite similar in all the higher animals. The subjects continue to grow to, or beyond, adult proportions but fail entirely to undergo the psychic changes of normal puberty. The resulting state represents essentially a persistence of a neutral asexual form rather than a transformation to the feminine form as popularly supposed. In some forms the rate of growth is somewhat retarded, but this may be masked by a tendency to lay on fat. The arresting of proliferation in the growth zones of the long bones fails to take place as in normal animals in the late puberal stage, hence the final stature is

likely to be greater than normal. Following castration the penis, prostate, and seminal vesicles cease to grow or, if the operation is delayed until the growth has taken place, a regression occurs. Relatively few influences on the metabolic processes have been detected though there is often seen a slight but sensible decrease of the oxygen consumption rate. This, however, may mirror relaxation of the subject rather than a depression of the true basal rate. Steinach[134] has recently reported that following castration the urinary creatine output is increased.

Aside from changes in the instinctual drives and emotional reactions no significant influence on the functions of the central nervous system has been noted but Wheelon[141] reported rather marked decrease in the irritability of the sympathetic nervous system of castrated dogs, an effect that was largely corrected by subsequent testicular grafts. The spontaneous activity of rats as measured in automatically recording exercising cages is markedly decreased by the operation.[68]

The relationship between the testes and psychosexual behavior is close. The common fowl is a favorable subject for experimentation directed to this problem. When the primary gonads are removed from either young males or females the result is an overgrown creature, the capon or the poulard, as the case may be. The erstwhile male remains timid, does not develop the masculine spurs or comb, and never crows. He shows no evidence of erotic interest in females. Particularly instructive is the fact that the poulard may subsequently regenerate functional gonadal tissue and this may be either testicular or ovarian. The bodily and dispositional changes appropriate to either sex then appear in accordance with the type of gonad regenerated. It thus appears that not only the quantity but also the quality of the gonadal hormonal influences are determined by the nature of the primary sex organs. This is a point of considerable significance in clinical psychopathology.

In the human species after early castration, the proliferative activity in the epiphyses of the long bones may continue well into the third decade whereas elongation of the trunk fails to take place in equal degree. Thus there develops a characteristic configuration, the arms and legs, hence the span and height, being quite out of proportion to the trunk length. The abnormal appearance is accentuated often by lean, long hands and fingers, toes and feet. The larynx remains small and of the infantile type, hence the voice remains high-pitched. The skin is delicate, pale, sallow, and liable to premature wrinkling which gives the subjects an appearance of early senility. The subjects are likely to be obese but even in the less common thin type the fat is peculiarly distributed. The sites of election are the buttocks, trochanters, breasts, lower abdomen, pubic region and lateral sides of the upper eyelids. The facial and body hair is scanty in amount and the pubic hair assumes the feminine pattern.

When castration is performed in the earlier years all genital development promptly ceases and potentia is never gained. When it is carried out after the sex functions are well established, a varying degree of sexual activity may persist. The effects of the operation on temperament in man have been much debated. Commonly the eunuch is reported as lacking in initiative and stamina. The mentality as such is apparently not affected. The instinctual drives are, of course, materially influenced, with all erotic propensities eradicated. Through the operation of disease and, particularly, as a result of

deficiency of the anterior pituitary, a condition of partial gonadal deficiency may arise. The effects approach those of castration, depending in part upon the time of onset of the disorder and in part on its severity. Two factors render a clean-cut appraisal of the effects of castration in man somewhat difficult. The stigma attached to the condition tends to make the individual self-conscious and to feel inferior. These factors may produce a profound effect upon the disposition quite aside from the hormonal influences. The second difficulty is that if the sex functions have become well established before the operation there is considerable tendency for them to persist. This topic has been discussed at further length in another publication.[70] The clinical aspects of gonadal deficiency in man are discussed at greater length by Lisser.[83]

Many attempts have been made to ameliorate the effects of definite or assumed testicular deficiency by the use of *grafts* or *gland extracts*. Indeed, the first formal experimental approach to endocrinology seems to have been made by Berthold when in 1849 he discovered the efficacy of bits of testicular tissue introduced into the peritoneal cavity in preventing the onset of the capon characteristics following castration in the fowl. The problem was taken up again in a systematic way by Steinach[133] early in the twentieth century. He removed the ovaries from female guinea pigs and replaced them with the sex glands of their twin brothers. These artificial males thereupon outgrew their female controls and showed the skeletal characteristics, the coarser hair growth and the pugnacity of normal males. The reverse experiment of feminizing castrated males by ovarian grafts was also successful. Steinach's work has since been confirmed by various other investigators, including Lipschütz,[82] who has reviewed the literature at some length.

The extent to which testicular grafts may be effective in the restoration of the waning bodily and sexual functions of old age is problematic. That many elderly men have testified to beneficial effects is unquestioned but to what extent results may have depended upon suggestion rather than hormonal influences is uncertain. In occasional cases, such as that of Lisser,[83] objective evidence of effectiveness has been obtained. In this instance a testis removed from a vigorous young man was transplanted into a man fifty years of age. The recipient had always been beardless; his voice was high-pitched, and it was stated that he had had no experience of sexual desire or activity. Within three months an awakening of sexual activity was reported. Objectively, the development of a beard and increased body-hair growth were noted.

The case for *testicular extracts* has until recently been little better than that for gland grafting. In 1889 Brown-Séquard,[25] then an elderly man, reported that injection of glycerin extracts of fresh testis into himself had had a remarkable effect in restoring his waning vigor. The experiment, however, has often failed of confirmation in the hands of other investigators and the chief significance of his report was the widespread interest that was aroused thereby in the subject of the internal secretions. Numerous attempts have been made by the use of testicular extracts of different sorts to overcome the effects of castration in experimental animals. While some successes have been reported many negative results have been secured. The literature is reviewed by Lipschütz.[82]

In the light of more recent work it would appear that the chief difficulty in the preparation of active testicular extracts has been the minute quantity in which the active principle occurs in the gonad tissue. The first successful

extraction of an active principle from testicular substance was reported by McGee.[92] The work was done in the laboratories of Moore and Koch who, with their collaborators, have reported numerous subsequent studies. The potency of the active testis extract can be demonstrated in a number of ways. The most practicable is to inject it into capons in which it causes striking growth of the comb, wattles, and other male head adornments. The response can be detected in one to three days, and regression of the comb promptly takes place when the extract is withheld. Funk and Harrow[47] succeeded in obtaining a similar active substance from the urine of men. They reported that it is absent from the urine of boys and of the aged. Similar success in the isolation of active material from urine was reported in 1931 by Butenandt[27] who succeeded in isolating it as a crystalline body and determining its composition. He gave it the name *androsterone* and assigned to it the formula, $C_{19}H_{30}O_2$. The same substance has been synthesized by Ruzicka and its composition confirmed. Study of this material soon indicated that it differed somewhat from the active principle of testicular extracts, and notably in its smaller activity per capon unit on the seminal vesicles of castrated rats. It appeared, therefore, that androsterone is not the chief principle of testicular extracts. David in 1935 succeeded in obtaining from testicular substance a crystalline body, which was of the sterol type, having high activity on both capons and rats. This he has named *testosterone*. It has the composition, $C_{19}H_{28}O_2$. Several other compounds chemically similar to these two have recently been prepared. It is proposed that all such substances having physiological potency be called *androgens*.[104] Deanesly and Parkes[35] have recently reviewed the literature on the androgens and have reported studies of their chemistry and relative potency. In general, the androgens all have the properties of causing comb growth in capons and preserving the seminal vesicles and prostate of mammals from the atrophic changes that normally follow castration.

From the fact that it occurs in testicular substance it may be surmised that testosterone represents a true hormone and androsterone a urinary excretion product. That the true testicular hormone is a compound of this type can scarcely be doubted, but in what precise form it is thrown from the glands into the blood stream has not and, from the types of study that have so far been made, probably cannot be determined. Both testosterone and androsterone are of high physiological potency. For example, 3 mg. daily of androsterone suffices to maintain normal seminal vesicle growth in mature rats. There is evidence that larger doses have a depressive effect upon the anterior pituitary, and that this in turn causes depressive effects in the testes of the intact animal. The therapeutic value of the androgens has not yet been adequately determined but they are effective in true hypogonadism.

That the testis has a true hormone function is further indicated in the rare cases in which neoplasms of those organs produce *sexual precocity* in the subjects. The classic case of Sacchi[119] is typical. Beginning at the age of five years the subject began to grow at a rapid rate and to develop the secondary sexual characteristics. At nine years of age he was 143 cm. tall with well-marked hair growth on face, extremities, and pubis, and the genitalia were approximately of adult size. During this period a carcinoma of the left testis underwent considerable enlargement. The affected organ was removed, whereupon the signs of sexual precocity rapidly receded. A few months later the beard

and hair on the extremities fell out, the penis became smaller, erections and ejaculations ceased, and the voice, which had reached low adult pitch, again became childish.

Numerous other instances of sexual precocity in boys have been reported but these, in general, have their primary origin in other endocrine organs—the adrenal cortex, the pineal, or the anterior pituitary. Commonly such cases are marked by excessive development of the genital organs, early deepening of the voice, and excessive body growth. Premature appearance of both the temporary and the permanent teeth is common. Genuine sexual activity, including the production of spermatozoa, has been reported even within the first year of life. The growth of the skeleton is at first stimulated but commonly the testicular hormone intervenes within a few years to stop the proliferative activity in the epiphyseal zones of the long bones, hence the ultimate stature is usually no greater than that of the normal adult and it frequently is materially less. The progress of skeletal maturing can readily be followed by x-ray studies of the wrist. Indeed, the progress of carpal ossification may serve as a "physiological time clock," to indicate the relative degree of physiological maturity in general (Todd).

The occurrence of *hypergenitalism* in the prepuberal years is unquestioned. Whether a comparable condition occurs in adulthood is curiously uncertain. There is a condition known clinically as *satyriasis* in which, as the name implies, eroticism goes to inordinate lengths. Whether this is due, however, to endocrine factors, to abnormality of the nervous system, or to social conditioning has not been satisfactorily determined. The fact that the testes are subject to depression of hormonal functioning during adulthood suggests, however, that hyperfunctioning also might occur. Fancher[42] has recently reported what purports to be the first case in the literature of authentic hypergenitalism in a man.

The evidence is now substantial that the testis under some conditions may exert a depressive hormonal influence upon the anterior pituitary. McCullagh[87] has reported the preparation of an extract believed to derive its potency from gametogenic tissue that has as its outstanding effect such a depressive influence. He proposes for it the name, *inhibin*. The work as yet lacks confirmation.

CHAPTER LXXV

THE OVARY

In addition to the production of ova, the female gonad also has important endocrine functions. At what stage the ovary begins to secrete hormone is not clear. That it initiates such secretion even before birth has been affirmed but positive evidence that this is true is largely lacking. Frank[44] by actual extraction methods was unable to detect any significant concentration of hormone in the prenatal ovary. Similarly scanty is the evidence regarding ovarian endocrinology during childhood. The young girl is largely neutral, sexually, but even during childhood some degree of feminine differentiation is manifested—particularly in the form of the pelvis. In view of the fact, however, that the two sexes differ in chromosomal constitution, such structural dissimilarities do not necessarily indicate the operation of hormone control. But with the onset of puberty the fundamental intervention of ovarian humoral factors becomes clear.

Ovarian Deficiency.—Gonadectomy is performed much less frequently in females than in males, but it is clear from animal experimentation that the operation in the prepuberal years causes a very similar persistence of neutral body form and lack of development of definitive reproductive instincts in either sex. The precise results of ovariectomy in the human species have been little studied, but in a few instances it has been noted that girls subjected to this operation become abnormally tall and fail to achieve development of the breasts; the axillary and pubic hair likewise fail to appear.

Through developmental anomalies, however, and particularly deficiency in anterior pituitary secretion, a condition more or less closely approaching that due to ovariectomy arises. The condition is often referred to as *female eunuchoidism* though the term is a misnomer; a preferable term is *sexual infantilism*. The condition is marked by a lag in the appearance of the puberal transformations and a halting of them short of completeness. Underdevelopment of the breasts, scantiness of pubic and axillary hair and persistence of the juvenile type of uterus and vulvar structures are the chief morphological indicators of the condition. Menstruation may be entirely absent or may be late in appearance and scanty in amount. The primary sex impulse and the secondary reproductive instincts are depressed.

In contrast with the paucity of data regarding the results of gonad deficiency in girls there is abundant evidence as to the effects of that condition in women. Following surgical removal of the ovaries at any age during the reproductive epoch the condition known as artificial *menopause* arises. Menstruation ceases; the uterus and breasts undergo regression. The subjects often increase in weight with an accumulation of adipose tissue especially in the region of the hips. A tendency toward masculine hirsutism not infrequently arises. The sympathetic nervous system goes through a stage of abnormal reactivity which leads, among other things, to periodic vasomotor changes in the skin. Subjectively these are experienced as "hot flashes." They can easily be induced by the administration of adrenalin, and it is not unlikely that

they are brought about or at least accentuated at times by episodic discharges from the adrenal medulla. That the central nervous system shares in the increased reactivity is indicated by emotional lability and often by a persistent sense of inner tension. In ovariectomized animals, the primary sex impulses are largely or entirely obliterated, but women who have undergone the operation report considerable degrees of variability in this respect.

In gynecological practice the occurrence of various manifestations which may plausibly be ascribed to functional ovarian deficiency is frequently noted in women who had previously attained normal development. These may or may not be associated with sclerotic or other regressive changes in the ovaries. Typically, the picture in the individual case is somewhat variable, a fact which suggests that the production of ovarian hormone may likewise vary from time to time. From the fact that ovarian deficiency as seen in childhood or in the postclimacteric period is a benign condition it seems probable that the symptoms of so-called *functional hypogonadism* in women are due rather more to imbalance of hormones than to pure deficiency.

Complete destruction of the ovaries deprives a woman not only of such hormones as may arise in the follicles and the interstitial tissue but of those in the corpus luteum as well. The differential effects may be studied by excision of the corpora lutea, leaving the other structures intact. This operation results in a disturbance of the functions having to do with pregnancy. If the operation is performed before or soon after fertilization, the uterus quickly loses its ability to fix the ovum, which passes through and is aborted. If the operation is deferred until *nidation* is under way, the embryo soon loses its functional relationship with the uterus and is aborted. While in some animals the presence of the corpus luteum is necessary throughout a considerable proportion of the pregnancy in order to forestall abortion, in women it becomes dispensable within the first month. A plausible suggestion is that the function of continuing the pregnancy is early taken over by placental hormones. This suggestion agrees with the fact that the placenta in the higher primates is a strikingly more prominent structure than in other animals.

Fraenkel (1901; 1903; 1910) was the first to provide experimental proof that the nidation and nutrition of the embryo depends on the corpus luteum. He showed that when the corpora lutea were removed from both ovaries of pregnant rabbits before implantation or at any time up to the eighteenth day, the pregnancy was terminated. From this it became apparent that the corpus luteum is necessary for the implantation of the ovum and for the maintenance of the proper uterine condition for the development of the embryo. It appears, however, that the necessity of the corpus luteum for the latter function varies in different species. In the guinea pig, for example, removal of the corpora lutea after the second day following coitus may not interrupt the pregnancy; this stands in contrast to the results obtained in the rabbit. It was shown by Leo Loeb that if any foreign body, such as a glass bead, is placed in the uterus at the time a corpus luteum is developing, a definite mass of decidual tissue is produced at the point of contact. Mere scratching of the mucosa has a similar effect. Deciduomata of this nature will not form if the corpora lutea are first destroyed. It would appear, therefore, that the ovum acts as a stimulus to a uterine mucosa which must be maintained in a certain state of nutrition and sensitization by the corpus luteum.

Ovarian Hormones.—The lines of evidence bearing on ovarian functions that have been derived from extirpational experiments have been supplemented in various important ways by studies of the influences of a variety of ovarian extracts and active principles. Some of these presumably represent veritable ovarian hormones though logically adequate proof that this is the case is not available in any single instance. Although previous investigators had made claims of having secured potent ovarian extracts, it was not until 1923, when Allen and Doisy[7] reported their results from the use of follicular fluid, that satisfactorily consistent evidence began to accumulate. These investigators showed that either the raw fluid itself or suitably prepared extracts from it have a marked influence in restoring the sexual functions and structures of spayed rats. From the fact that the animal is again brought into estrus, the active principle found in the follicular fluid has been designated as *estrogenic*.

Fig. 363.—Effect of injection of follicular extract into eight-week-old rabbits. Animals were litter sisters. No. 807 received 2 mg.; No. 805, not injected, was killed at the same time as No. 807 for control. No. 806 received 1 mg. daily for four days and No. 809 1 mg. daily for eight days. No. 808, uninjected control, killed on same day as No. 809. (After Doisy, Ralls, Allen and Johnston.)

As a matter of fact a considerable number of preparations have estrogenic properties. The literature on this subject has become extensive and many technical details regarding such substances are now available, but the interrelationships and the physiological significance of the several estrogenic materials have not as yet become clearly known. Animal sources of estrogenic material other than the ovary itself are the urine of nonpregnant women; the blood, urine and amniotic fluid of pregnant women; the human placenta; the urine of pregnant mares and of stallions; and the urine of men with testicular neoplasms, especially teratomata. Similar materials have also been derived from plant sources. Not only may the estrous reactions be induced directly by these various substances, but they may be secondarily set up by hormones from the anterior pituitary, the placenta and perhaps other endocrine glands which stimulate the ovaries.

In addition to arousing the mating impulse of the female animal the estrogenic hormones have the property of inducing rapid growth in the accessory genital organs (Fig. 363). Changes in the vaginal wall are especially characteristic, a fact that has led to the widespread use of vaginal changes in rodents for the assay of estrogenic materials. These changes can readily be detected by examination of the vaginal fluid. Other effects that can be elicitable are changes in the plumage of certain birds, reddening and swelling of the sexual skin of various higher primates, growth of the mammary glands and proliferation of the endometrial wall. The latter change is accompanied by vasodilatation of the capillaries. The muscular activity of the uterus and the fallopian tubes appears also to be controlled by estrogenic hormone. Coincident with the oestrual increase of the sex urge there is also an augmentation of spontaneous bodily activity.

The threshold of reactivity to estrogenic substances varies in different structures. In rats and mice more is required to bring about endometrial proliferation than changes in the vagina and to elicit the mating reactions requires a still greater amount.

The appearance of estrogenic material in the urine of women varies in relation to the menstrual cycle; the curve of hormone concentration shows two peaks, the first and smaller occurring about the mid-menstrual period and the second in the early part of the last week preceding menstruation. The first peak is apparently correlated with the maximal growth of the follicle and the second with the height of corpus luteum activity. During pregnancy there is a gradual rise in the excretion of estrogenic substances. The output becomes clearly apparent in the latter half of the second month and continues throughout the period of gestation. After parturition the level of excretion falls rapidly to reach the normal value within four or five days. Further details of the physiology and pharmacology of the estrogenic principles are available in a review by Allen[6] in which are cited several important monographs.

A considerable number of potent estrogenic materials under a variety of names are available commercially (Biskind[18]). The activity of these is due in whole or in part to certain active principles now available in crystalline form. The first to be obtained was *theelin,* $C_{18}H_{22}O_2$. This is designated also as *ketohydroxyestrin,* or *oestrone.* Somewhat less active when administered by subcutaneous or intramuscular injection but more potent when taken by mouth is the trihydroxy compound *theelol* or *oestriol,* $C_{18}H_{24}O_3$. For further information on the somewhat complex chemistry of the estrogenic principles recent monographs should be consulted.[6, 10, 57]

The estrogenic hormones are used therapeutically in a variety of conditions authentically or presumably due to deficiency of the ovarian secretions. They have proved to be most valuable in correcting certain menstrual abnormalities and amelioration of the subjective symptoms of the menopause—naturally or surgically induced. Numerous instances of successful results in the treatment of psychoneurotic symptoms other than menopausal have also been reported but an evaluation of the effects of the preparations, as distinct from the effects of suggestion, is difficult. Commonly, women are reported to recognize no influence of estrogenic preparations on the primary sex urge, but in occasional instances such effect is reported to be rather marked.

The relationship of the corpus luteum to pregnancy as indicated by the results of extirpation experiments has been largely confirmed by a study of effects of chemical derivatives of corpus luteum tissue. As a generic term for the active principles in such extracts the name *progestin* has been suggested.[103] One progestin has been obtained in crystalline form, and this is properly referred to as *progesterone*. This is a diketone having the formula, $C_{21}H_{30}O_2$. The synonym, *luteosterone,* is frequently used in the European literature. Progesterone exists in an alpha-form melting at 128° C., and a beta-form melting at 121°. The physiological significance of this difference is not known. Chemically, progesterone is closely related to the estrogenic principles as well as to the male hormone, androsterone; it is structurally similar also to certain cyclic compounds having carcinogenic properties.

Progesterone is not potent when given by mouth, either because of failure of absorption or because of inability to withstand the digestive enzymes; it is commonly administered intramuscularly in oil. It is assayed in terms of its ability to produce in castrated rabbits the uterine changes characteristic of pregnancy. The induction of progestational changes in the uterus can be obtained only if the uterus has first been "primed" by estrin. Progesterone has the property of preventing abortion following extirpation of the corpus luteum and permitting the pregnancy to run to full term. In some forms, notably the guinea pig, it demonstrably serves as a stimulus for the production of the maternal part of the placenta. Different observers have succeeded in producing with progestin the premenstrual type of endometrium in monkeys. In ovariectomized women after preliminary treatment with estrogenic substance progestin is able to bring about the further normal premenstrual changes. Progestin has an inhibitory effect upon the uterine musculature; the favorable influence of the material that has been reported clinically in forestalling threatened abortion may be correlated with this property. The part that progestin plays in the menstrual phenomena will be discussed in a subsequent section.

Whether the ovaries ever secrete estrogenic hormone in sufficiently excessive degree in adults to give rise to significant clinical effects is uncertain. The condition of *nymphomania* with its excessive sexual urge might plausibly be ascribed to such a cause, but the element of abnormality of the nervous system is difficult to exclude. A considerable number of well authenticated cases of precocious puberty in girls have been reported and this for the age in which it occurs amounts, of course, to *hypergonadism*. While the condition is more commonly due primarily to disturbances in other endocrine glands it may have its primary origin in the ovaries themselves. In veterinary practice abnormal persistence of the corpus luteum, usually in cystic form, is a well recognized cause of sterility. This is brought about by the halting of the sex cycle at the phase which is dominated by progestin. There is some clinical reason to suppose that a similar situation in women may give rise to sterility.

In the foregoing discussion considerable simplification has been made. The action of the ovarian hormones as well as their production is in considerable measure determined by conditions in related organs. Some of the complicated relationships that are involved will be discussed in the next chapter.

CHAPTER LXXVI

ENDOCRINE FACTORS IN REPRODUCTION

That the reproductive activities are under endocrine control has been indicated in various preceding paragraphs. The relationships involved are notably complex and may be further discussed from the standpoint of the various reproductive functions, themselves.

It is probable that normal *sexual development* cannot occur in the serious deficiency of any of the important hormones. In some cases these seem to be important primarily if not solely in their function of assuring a sufficient degree of metabolic and nutritional normality to support the biological processes involved in sexual development. In other instances the relationships appear to be specific.

One of the striking results of *thyroid deficiency* is a general retardation of development in which the sex organs and reproductive instincts share. The gonads themselves and the accessory reproductive structures remain small or, in lesser degrees of thyroid deficiency, show a lag in development. In women in whom menstruation has become well established high degrees of intervening thyroid deficiency may lead to depression of the function but with lesser degrees profuse and abnormally frequent flow is more likely to be seen. In such cases thyroid medication often corrects the menstrual abnormality. In males who have achieved sexual normality the intervention of thyroid deficiency leads to decreased libido and various degrees of impotency. In both sexes sterility that is subject to amelioration by thyroid medication may arise.[99]

The sexual precocity following the use of *thymus extracts* as reported by Rowntree[117] may be indicative of a specific hormonal control of reproduction but various investigators have failed to confirm the findings.

Whether the *parathyroid glands* have any important relationships with reproductive activities is not evident.

In the case of the male the reproductive activities are relatively simple and the known hormonal factors involved in their control have been previously indicated. The relationship between the testis and the *pituitary* is particularly close. In the case of early anterior lobe deficiency normal development of the gonads cannot take place; if such development has been achieved prior to the onset of the pituitary deficiency, functional activity cannot be maintained. A partial exception to the foregoing statement is that in certain instances the secretion of gonadotropic hormone may persist when the production of somatotropic hormone is deficient, i.e., pituitary dwarfs are occasionally fertile. Experiments on parabiotic rats have afforded evidence that castration removes a check on the anterior pituitary and so leads to an increase in its production of gonadotropic material. Also, implants of anterior pituitaries from castrated animals show greater than normal gonadotropic potency. The theory has been advanced that the activities of the two glands are kept adaptively in balance; the rate of production of testicular hormone serves to determine that of the con-

trolling pituitary secretion and vice versa. Antecedent changes in the anterior pituitary probably play an important rôle in determining the seasonal periodicity of the reproductive activities of many animals.

The hormonal relationships involved in the reproductive activities of women are more complex than is the case in men. As previously mentioned, there is some probability that ovarian hormones determine in some measure the bodily form of the girl as contrasted with that of the boy, but it is not until the onset of puberty that hormone intervention becomes clearly evident. The bodily and psychological changes of puberty take place only as adequate supplies of primary gonadal hormones are available. The secretion of these hormones is in turn dependent upon the gonadotropic hormones of the anterior pituitary. Throughout childhood the ovaries in periodic succession continue to produce maturing graafian follicles, but these fail to dehisce; they undergo regressive

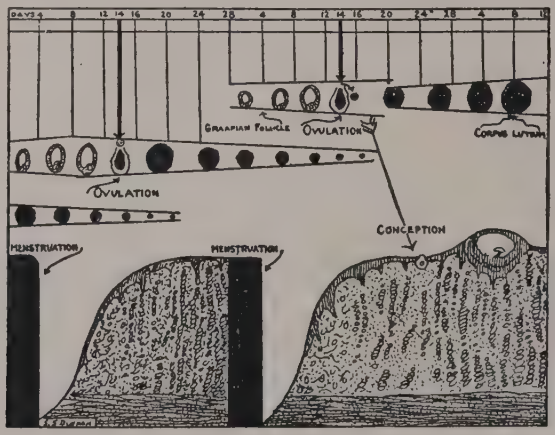

Fig. 364.—Diagram showing the relationship between the ovary and the uterine changes of menstruation and pregnancy. The lower part of the diagram represents the endometrium with its contained glands. Note the nidation of the early embryo and, further to the right, the attached embryo and beginning placenta formation. Courtesy of Dr. Benjamin Parvey. Published in Endocrinology, 16: 225, 1932. (From Hoskins: The Tides of Life, New York, 1933, W. W. Norton and Company.)

changes and their contents are absorbed. At about the twelfth year, in temperate climates, and a few months earlier, in the warmer countries, one of the follicles ruptures at the surface of the gonad, liberating an ovum. Fertilization now for the first time is possible and the transition point from puberty to adulthood has been passed. This transition is objectively signalled by the onset of menstruation.

Menstruation.—The menstrual cycle may conveniently be divided into four periods: the resting stage, the interval stage, the premenstrual stage, and the destructive stage.

The *resting stage* comprises the four or five days immediately following the cessation of the preceding flow. During the flow the lining tissues of the uterus are to a considerable extent broken down and discharged. Consequently at the beginning of the resting stage the mucosa is very thin. The uterine glands are

relatively sparse, narrow and straight. At this stage the ovary contains a corpus luteum formed in the previous cycle, but its secretory function is now on the wane. It is diminishing in size and losing its characteristic yellow color to become a little later the corpus albicans, a structure that so far as is known has no active function. During the resting stage a new graafian follicle is progressing toward dehiscence and forming follicular fluid with its contained hormone—presumably theelin. The best evidence indicates that the production of theelin at this stage is shared by the surviving corpus luteum.

The *interval stage* of the cycle lasts about ten days. It is a period characterized by adaptive changes in the uterus preparatory to the reception of the next ovum that may be discharged. The endometrium rapidly thickens and the uterine glands lengthen and permeate more widely through the endometrium; the blood supply increases to a marked degree. Coincident with the growth of the endometrium, activities in the ovary continue. Within the first half of the interval stage the follicle ruptures. Thus ovulation occurs about midway between the menstrual periods. At this time the production of theelin is at its height. Immediately after discharge of the ovum, rapid multiplication of the cells lining the follicle ensues to give rise to a new corpus luteum. The newly formed lutein cells begin, presumably at once, to form progestin, whose influence on the uterus is now added to that of the theelin. The weight of available evidence indicates, however, that the corpus luteum at this stage participates also in the formation of theelin. The newly discharged ovum enters the fallopian tube through which it is swept along toward the uterus. It is now ready for fertilization, and if a spermatozoon is available the two gametes fuse to give origin to the embryo. Although clean-cut data on the point have been difficult to secure, considerable evidence is now available that, at this period when the production of ovarian hormones is at its height, the woman experiences an accentuation of sexual desire. In the subprimate forms it is at this point in the ovarian cycle that the phenomena of *estrus* occur. Commonly in these forms it is only at this time that the male is accepted.

Succeeding the interval stage is the *premenstrual stage,* ten days in duration. Under the further influence of the ovarian hormones the preparatory processes in the endometrium continue. The uterine glands increase in diameter and in length and assume the characteristic corkscrew form. They become distended with secretion. The relative parts played by the estrogenic and luteal hormones at this period are somewhat uncertain, but probably the latter assumes the dominant rôle. In the latter part of the premenstrual stage the endometrium has reached its maximum degree of preparedness for the prospective pregnancy. If fertilization occurs, the corpus luteum continues to secrete at a maximal rate and brings about the changes characteristic of pregnancy. On the other hand, should fertilization not occur, the hormonal activities of the ovary and corpus luteum rapidly wane and the endometrium, deprived of their stimulating influence, begins to regress. This point marks the onset of the destructive stage when the menstrual flow begins. From the congested capillaries of the endometrium diapedesis occurs. The parts of the endometrium nearest the lumen of the uterus begin to break down and with their disintegration the capillaries rupture and the menstrual flow becomes fully established. During the four days that normally comprise this period, the dismantling

processes in the endometrium are completed, the detritus is all discharged, the ruptured blood vessels are closed and the succeeding cycle begins.

The processes just described comprise the common type of menstruation. In monkeys, however, another type, anovular menstruation, has been demonstrated to be of rather frequent occurrence and accumulating evidence indicates that this type also occasionally occurs in women. Presumably the earlier hormonal activities are approximately the same in both types, but in the anovular the ovum is retained within the follicle which thereupon becomes atretic without the formation of a corpus luteum.

The foregoing sequence of events serves to fix the period of fertility in women. From observations made in the course of laparotomies and, more recently, by direct study of the time of apearance of ova in the fallopian tubes, the time of ovulation has been rather definitely fixed. Allen and Pratt[8] have developed a technique of washing out the tubes exposed at operation. They have not been able to recover ova earlier than the twelfth day nor later than the sixteenth day after the beginning of the preceding menstrual flow. The appearance of the ova themselves, as well as signs of recent rupture of ovarian follicles, served to complete the evidence. The time of ovulation, therefore, occurs at the midmenstrual period, and fertilization is possible only during the brief period that the ovum is in the fallopian tube or uterus from which, unless it is fertilized, it is soon discharged.

The most uncertain feature in determining whether a given coitus may be fruitful is the possible length of survival of male gametes within the genital tract of the female. The earlier belief was that spermatozoa might persist in a state of functional efficiency for as long as ten days after coitus, but the more recent and more reliable evidence indicates that the period is much shorter.[6] In the case of women, therefore, who enjoy regular menstrual cycles the "safe period" may be relatively accurately fixed. Considerable irregularity, however, is not uncommon, and the possibility is perhaps not wholly excluded that the act of coitus, itself, may lead to precocious ovulation. In the rabbit, indeed, ovulation takes place only after coitus, the immediate stimulus being a discharge of anterior pituitary gonadotropic hormone brought about as a nervous response to that act.[22]

Many women report a sense of well-being and efficiency during the midmenstrual period at the time when the hormone output from the ovary is at its maximum level. At this time, too, the oxygen consumption rate is at its high point for the given cycle. It then falls off to reach its minimal level at the time of the flow. During uterine bleeding, when hormone production is at the lowest level, many women experience a sense of tension and irritability. This may be accentuated by dysmenorrhea but it seems to occur even when local pelvic pain is absent. It is known from animal experimentation that deficiency of ovarian hormone causes an augmentation of sympathetic irritability and the brain seems to share in this characteristic.

That the periodicity of the menstrual phenomena depends upon variations in the rate of secretion of ovarian hormones is clear. The cause of the periodicity in these secretions resides largely in the anterior pituitary. As previously pointed out, this structure and the ovary stand in functional relationship whereby an ebb in the ovarian hormone tide serves to bring about augmented secre-

tion of gonadotropic hormone. This causes increased ovarian activity which in turn brings about a depression in the anterior pituitary. The lag in these reciprocal responses gives time for successive waves of activity; without this lag, the two structures would presumably come into equilibrium and the periodicity disappear. There are suggestions in the recent literature that the relations of the corpus luteum and of the ovary, proper, with the anterior pituitary are more or less independent, hence the foregoing reasoning would apply to these structures individually rather than to the ovary as a whole. This principle could account for the fact that the two hormones are in some respects antagonistic and in others synergistic in their end effects.

Pregnancy.—Menstruation seems to be contingent upon sudden cessation of ovarian hormone production. This, in turn, results in some unknown way from failure of fertilization of the ovum. If, on the other hand, fertilization does occur, a different train of events ensues. The corpus luteum instead of undergoing regression continues as an actively secreting structure. The endometrium that had been prepared for the process of *nidation* continues its development toward placenta formation. From the fact that after the third week of pregnancy in women destruction of the corpus luteum fails to cause abortion it is obvious either that no further hormone stimulation is needed or that some other source of stimulating hormones comes into action. The available evidence suggests that this source is the placenta. At any rate placental extracts can be separated into fractions of which one is estrogenic and two others possess gonadotropic properties resembling those of anterior pituitary extracts.

When the fertilized ovum reaches the uterus it soon acquires an attachment to that structure. This fixation, nidation, is dependent upon the preceding hypertrophic changes of the endometrium. The outer envelope, the chorion, undergoes rapid development, penetrating the uterine wall and giving rise to the fetal portion of the placenta. According to the best of the evidence the chorionic structures begin to secrete hormone even during the first month of pregnancy and continue this secretion in increasing amounts to the time of parturition. Under its influence together with that of the ovarian hormones and, apparently, of an additional hormone from the anterior pituitary, the various adaptive changes correlated with the pregnancy take place. These changes include modifications of the maternal metabolism to permit the nutrition of the growing fetus and the elimination of the excess waste products of fetal origin. Whether the adaptive mechanisms include changes in the maternal endocrine glands whereby the fetal development is regulated presents an important problem that has been but little studied. The tendency toward thyroid hypertrophy during pregnancy suggests that reactions may occur in other glands. At any rate it is not until the pregnancy is fairly well along toward completion that the endocrine structures of the fetus itself reach a stage of functional efficiency.

The most striking maternal reaction is a continuation of the hypertrophic changes in the uterus itself. The muscular wall undergoes marked increase in bulk, principally by enlargement of the individual muscle cells. Coincident with the uterine changes the walls of the vagina expand and become more vascular and the lubricating secretions increase in amount. Further details

regarding the pelvic alterations during pregnancy may be found in textbooks of obstetrics. The endocrine factors are clearly discussed by Hamblen.[57]

It is not improbable that were technical methods for their quantitative determination available changes in the titer of a variety of hormones in the blood might be detected during the progress of the pregnancy. It is now possible to show that the theelin content of the blood rises progressively from early pregnancy to parturition, at which time the titer is considerably higher than during the premenstrual phase of the sex cycle. Not only is the estrogenic material demonstrable in the blood but the same or a similar active substance is discharged in increasing amounts through the kidneys. Whether, however, the urinary theelin represents true hormone that is formed in excess or whether it is to be regarded as an excretory product is a matter that is still in debate. As previously mentioned, we have only presumptive evidence regarding the precise chemical form in which the sex hormones are discharged into the blood. In any case it can be stated that the excretion of estrogenic material increases from somewhat less than one thousand "mouse units" per liter of urine during the first month to approximately ten thousand units in the last month. The urine of pregnant women is one commercial source of estrogenic material. This high urinary output may be correlated with the relatively great development of the human placenta. In most other primates this organ is relatively much smaller and the renal output of estrogenic material little or none. By injecting suitable extracts of the blood serum of pregnant women into immature mice a marked hypertrophy of their genital tracts can be induced, a fact that is interpreted as indicating an increased maternal production of anterior pituitary gonadotropic hormone. This active substance, too, is discharged in considerable amounts in the urine; it rises progressively to about six thousand mouse units per liter in the fifth month, then gradually declines to about half that amount in the last month of pregnancy. The material ceases to be excreted shortly after parturition.

It is the appearance of these active anterior pituitary-like substances in the urine that makes possible the various tests for pregnancy. In these, mice, rats, or rabbits can be used. The urine itself or a suitable extract is injected and by inspection of the ovaries and the uterine horns of the recipient test animals a day or so later the presence or absence of the stimulating substance can be determined. Positive tests may be secured within the first month of pregnancy. The test is highly reliable but "false positives" may be obtained in certain cases of neoplasm, and particularly in cases of hydatidiform mole.

The evidence regarding the possible relationships of the various other endocrine glands to pregnancy has been discussed at greater length in another publication.[69] The reciprocal maternal-fetal hormone relationships are in need of further study.

It appears, then, that pregnancy is a condition exquisitely dependent upon endocrine factors. The preparatory changes preceding the pregnancy are regulated by the joint action of the ovarian and the corpus luteum hormones and the production of these is in turn dependent upon the influence of pituitary hormone. The inception of pregnancy is dependent upon a degree of normality in both the parents sufficient to assure fertility. After pregnancy is initiated structural changes occur in the pituitary and the thyroid which suggest that

these organs are undergoing compensatory activity. Scanty evidence suggests that adaptive reactions occur also in at least some of the other endocrine glands. The placenta apparently also functions as an endocrine gland producing important regulatory hormones.

Lactation.—The *mammae* are skin glands that have undergone a specialized development. They first become evident in the fetus as a thickening of the skin to form a ridge, the mammary line, extending on each side along the ventral body wall. In many of the mammals the mammary line breaks up into several nodes of development but in the human species ordinarily only a single region toward the cephalic end of each line continues past the rudimentary stage. The occasional occurrence of accessory mammae in women apparently represents a throw-back to the earlier developmental pattern. The proliferation of the growth node results in an inwardly directed sproutlike structure which branches until the total constitutes a fairly complex "duct system." In some species the ducts all converge to a single conducting unit corresponding to the trunk of a tree. In others several branches end independently at the tip of the nipple. In man there are about a dozen such primary ducts. In the further development the ducts enlarge toward their distal ends to form the milk cisterns. The secreting epithelium appears at the terminations of the ultimate branches of the duct system. At the time of birth in the human species only a small amount of such glandular tissue has appeared but enough to permit the secretion of the "witch's milk." Apparently this fluid is formed as a result of the same hormonal stimulation that causes activity in the maternal glands. After severing of the umbilical cord with consequent deprivation of the stimulating hormone the secretion soon ceases.

At birth the mammae of both sexes are similar in structure and stage of development. In males essentially the infantile condition persists throughout life. In girls, however, the onset of puberty is signalled by further development of the mammae. The glandular cells increase in number and size, and fat is laid down in increasing amounts in and around the glandular and duct tissue. The mammae of the adolescent girl, as a matter of fact, consist mostly of fat.

The precise details of the hormonal factors in mammary development in man are as yet largely unknown but there is rather an extensive literature on the relationships in animals from which various plausible deductions can be made as to human conditions.[6, 57]

The prepuberal evolution of the glands comes about chiefly under the stimulating influence of ovarian estrogenic hormone, as is shown by the fact that extirpation of the ovary precludes its occurrence. Since the evolution proceeds to a considerable extent before the onset of corpus luteum formation, hormones from that structure are not primarily involved. It is possible, however, to bring about a considerable development of the mammae in young adult, ovariectomized rabbits by the use of alkaline extracts of the anterior pituitary, hence pituitary hormone presumably plays a significant rôle at this time.

With the onset of pregnancy, the mammary glands, which had reached a resting stage after the puberal evolution, undergo renewed activity. The secretory epithelium further proliferates and at the end of pregnancy the cells are well charged with the precursor substances from which the milk is

formed. During this phase of development the corpus luteum presumably plays a significant, stimulating rôle. In animals, through the successive administration of the estrogenic and the corpus luteum hormones, mammary development can be carried to the lactation phase either in immature females or in males. The burden of the evidence, however, is to the effect that the final stage of lactation, i.e., the breaking down of the mammary cells and the dilution of their contents with water from the blood, is, primarily, if not exclusively, under the control of the special anterior-pituitary hormone, prolactin. The fact that in women amenorrhea is of frequent occurrence during the first few months of lactation suggests that prolactin may have an inhibitory effect on hormone production in the ovary. At the conclusion of the nursing period the mammae revert to approximately the late puberal condition.

At the conclusion of the reproductive epoch in women the mammary glands undergo considerable atrophy. To what extent this is merely a special phase of generalized tissue regression and to what extent it represents a waning of hormonal secretion have not been satisfactorily determined.

The Menopause.—The active reproductive period in women terminates at approximately the forty-seventh year, in the menopause or climacteric. In the individual case this may occur a few years earlier or a few years later than forty-seven.

The manifestations of the menopause are quite variable. In some instances the onset is insidious and the transition is marked only by increasing irregularity of menstruation until it finally ceases; in other cases the onset is abrupt. The climacteric may be accompanied by few perturbations or by such distressing symptoms as irritability, difficulty in concentration, mental depression, restlessness, and insomnia. These manifestations may become so marked as to constitute the psychosis, involutional melancholia. The symptoms may be of brief duration or may persist for months or years; they may be recurrent with intervals of approximate normality. The participation of the sympathetic nervous system in the production of the symptoms of the menopause, especially the "hot flashes," was mentioned in an earlier paragraph. Although the usual course of onset is a gradual lessening of the menstrual flow the climacteric may be ushered in by a period in which profuse flow occurs.

The menopausal picture ensues when the ovaries are removed at any time after puberty is established, and it can be induced by the application of radium to the ovaries. The symptoms of the induced menopause are likely to be more acute and abrupt in onset than when the condition arises spontaneously. The primacy of ovarian failure in the causation of the symptoms is indicated by their prompt onset after ovariectomy. Whether other endocrine structures participate significantly has not been satisfactorily determined. Some authors report evidences of overactivity of the thyroid gland at this time, but others have found precisely the opposite condition. The fact that the basal metabolic rate ordinarily shows no significant depression rather points toward the absence of thyroid deficiency as a contributory factor.

A tendency toward masculinization at the climacteric has often been noted. This is indicated by increased growth of hair on the face and especially on the upper lip, a lowering of the pitch and a change in the timbre of the voice, and perhaps a significant degree of change in the temperament. These

tendencies suggest accentuated function of the adrenal cortex, but satisfactory objective evidence of this is lacking. In view of the intimate relationship between the ovaries and the anterior pituitary it might be anticipated that the latter would undergo significant morphological changes at this time. Such, apparently, is not the case. The functional evidence, however, is somewhat more indicative of coincident change in hypophyseal activity. In a considerable proportion of women it has been possible to demonstrate an increased amount of the follicle stimulating hormone in the blood and it occurs rather regularly in the urine. The occasional occurrence of mild acromegalic changes at the menopause may be construed as further evidence of overactivity of the anterior pituitary.

The evidence regarding the utility of ovarian preparations in the alleviation of the climacteric symptoms is notably lacking in consistency. The element of suggestion demonstrably can play an important rôle and in many of the studies that have been reported suggestion has not been adequately excluded as the chief or only cause of improvement. Since the purified active principles have become available, however, the evidence has become somewhat more convincing. Thus Werner and his associates[140] in an extensive and well-controlled series of clinical experiments have reported marked amelioration even when the symptoms have reached the severity characteristic of involutional melancholia.

From the fact that the nervous manifestations of the menopause gradually cease it would appear that the symptoms are due rather more to a hormonal imbalance than to ovarian deficiency, as such. For a more extensive discussion of this and similar topics Mazer and Goldstein,[98] and Hamblen[57] may be consulted.

Sterility.—Sterility may be due to any functional or mechanical condition that prevents the introduction of spermatozoa into the vagina or access of these gametes to the ovum. Similarly, nutritional or other abnormalities that prevent the formation of viable gametes will cause sterility. For the operation of the various nonendocrine factors the textbooks of gynecology may be consulted. This discussion will deal only with the hormonal abnormalities that may prevent either conception or the development of the fertilized ovum.

It should be emphasized that infertility is a relative condition. Numerous cases are on record of sterile matings in which both partners were subsequently proved to be fertile. Infertility ranges in the various cases from slight to absolute. If both parties to a given mating are highly fertile, pregnancy results promptly and repeatedly, unless effective contraceptive measures are employed. If both are of relatively low fertility the matings will be either entirely unfruitful or only occasionally successful.

Infertility may be due to incomplete development of the reproductive organs or to a secondary decrease in the vitality of the gametes. In women, actual persistence of the early juvenile conditions is relatively rare, but in many cases development halts at the pre-adult stage. The common cause of this halting, according to Meaker,[99] is relative deficiency of either the pituitary or the thyroid gland at the hebetic epoch. This period having passed, the deficit seems to be overcome and, adult years having been reached, no further signs of hormone deficiency may be evident. But the underdevelopment of the reproductive organs tends to persist as a permanent handicap to fertility. Ovula-

tion may fail entirely or be infrequent; likewise, the ova that are discharged may be incapable of being fertilized. In men, comparable persistence of juvenile conditions is usually not objectively evident but the spermatozoa that are produced may be of such low viability as seldom or never to complete a normal fertilization. In Meaker's experience the most common endocrine disorder that causes sterility in women is deficiency of the anterior pituitary. Evidences of this abnormality were found six times as frequently as those of primary ovarian deficiency. Thyroid deficiency occupied a middle ground. Statistics on the relative frequency of similar glandular defects in men are not available. Attempts to correct infertility by endocrine medication have been most successful from the use of thyroid substance. Potent gonadotropic pituitary extracts have not been available for a sufficient period to permit the accumulation of definite statistics on their value. Ovarian preparations have proved to be of relatively little use.

CHAPTER LXXVII

PINEAL, THYMUS AND OTHER POSSIBLE ENDOCRINE ORGANS

THE PINEAL GLAND

Despite a great deal of investigation the status of the pineal gland as an endocrine structure remains somewhat indeterminate. In some vertebrate species it seems to be merely a vestigial organ, while in others it is a fairly distinctive morphological structure. Microscopically, it presents relatively little evidence of having a secretory function. It is made up largely of supporting tissue, but it contains a considerable amount of pigment, some lipoid material and, in some species at least, shows cells that bear a resemblance to secreting epithelium. In many forms it has a rich blood supply which suggests the possession of functional activity.

Many negative results have been secured from the administration of *pineal extracts*. When injected directly into the blood stream such materials cause a fall of blood pressure and sometimes passing polyuria, but since similar results may be obtained from indifferent tissue extracts, they have slight weight as evidence of hormonal function.

Recently Hanson has succeeded in making an acid extract of pineal tissue which, in the hands of Rowntree and his associates,[118] has yielded somewhat striking results. The extract was administered intraperitoneally each day to successive generations of parent rats, and the effects upon both parents and offspring were noted. Following its use, breeding occurred more frequently and, in succeeding treated generations, both the birth-weight and the rate of growth were increasingly depressed, but the rate of differentiation and development was accelerated. In the fifth generation of treated animals the average young rat was of less than half normal weight, was sexually mature at approximately half the normal time and evidenced marked precocity in the development of fur, eruption of the teeth, and opening of the eyes. These results are set forth as representing true experimental *dwarfism*. The fact that the influence of the extract was cumulative through succeeding generations represents an unusual biological happening and suggests the necessity of accumulating more than the ordinary weight of evidence. The offspring showed diminution of general vitality as indicated by high mortality rate and lack of vigor, but in some instances the frequency of littering was remarkable, the interval between litters being as short as twenty-three days. As to the effect of the Hanson extract in human subjects no data have as yet been reported. There is a clinical condition which is marked by persistence of growth well beyond the normal age of maturity and accompanied by lag of sexual development. For this condition a hormone having the properties reported for pineal extract would offer considerable promise of clinical usefulness.

Pineal feeding in the hands of most investigators has given equivocal or negative results, though McCord[88] reported a generation ago that the develop-

ment of puppies was somewhat accelerated by the administration of desiccated gland substance from calves. That such material is not entirely devoid of physiological potency is indicated by the results of McCord and Allen[89] who added desiccated pineal substance to the water in which tadpoles were kept. This caused a sharp contraction of the melanophores, giving the animals a strikingly peculiar silvery translucent appearance. The observations have been confirmed by Addair and Chidester[2] who added the observation that metamorphosis was hastened.

Pinealectomy has commonly given negative results. The operation is difficult and the mortality is high. Izawa,[75] however, confirming the positive results of a few earlier observers, reported that destruction of the pineal resulted in accelerated development in rats of both sexes. Two months after the operation the gonads were found to be approximately a fourth larger than in the control subjects.

Some further evidence on the presumptive endocrinology of the pineal is derived from the study of the clinical condition, *macrogenitosomia praecox*. Although the disorder has been written upon at length, the actual recorded number of proved cases is rather small; Haldeman[56] in 1927 was able to find accounts of but sixteen. All occurred in males and the disorder was first detected in the various instances from the ages of three to sixteen years. It was marked by a precocious development both of the body and of the sex organs. In a typical instance a five-year-old subject was described as a "Hercules in miniature," burly in figure with the low-pitched voice, beard, and sex organs of an adult. A somewhat comparable degree of mental maturity has been occasionally reported. In addition to the proved cases a considerable number have been reported in which pineal involvement was presumptive only. Whether the association of precocity with pineal tumor indicates a genuine hormone function or whether the precocity is due merely to the mechanical influence of the neoplasm on contiguous nervous structures has been much debated without reaching unanimity of opinion. The evidence, on the whole, is inconsistent. Izawa's work suggests that deprivation of the gland releases the developmental potential of the animal, whereas pineal tumors, supposedly productive in type, seem to have a similar effect. The Hanson extract caused depression of growth but acceleration of sexual development. Obviously more evidence is needed.

THE THYMUS GLAND

A somewhat similar lack of definite evidence confronts one in a consideration of the literature on the thymus. That animals can survive in good health complete extirpation of this organ has been abundantly proved. On the other hand, animals lacking the gland seem to be abnormally sensitive to environmental stresses and particularly to malnutrition or suboptimal vitamin intake. Under the combined influence of *thymectomy* and unfavorable environmental conditions a generalized stunting has frequently been reported, with failure of mineralization of the bones as an outstanding feature. The subjects are apathetic and in some cases have been reported to show a condition comparable to imbecility in man.

In the literature two correlations stand out with rather impressive consistency, namely, thymus enlargement following *castration* and a similar hyper-

trophy under conditions in which diminution of the adrenal cortical function occurs. Grollman[53] has noted the consistent occurrence of *status thymico-lymphaticus* in chronic *adrenal deficiency*. This coincidence acquires special weight from the fact that the thymus is a labile structure that atrophies quickly under most conditions of malnutrition, whereas malnutrition is a prominent feature of adrenal deficiency. Presumptive evidence of an antagonistic relationship between the gonads and the thymus is seen in the fact that the latter structure achieves its maximum relative weight during the prepuberal period and then recedes as the gonad hormones begin to function prominently.

Several investigators have reported that *thymus feeding* causes a marked change in the metabolism of tadpoles. Metamorphosis and sexual development are markedly delayed and overgrowth during the persistent larval stage occurs. Some investigators have regarded this merely as a nutritional phenomenon but Gudernatsch[55] who has extensively reviewed the literature believes that a thymic hormone is involved. Riddle[112] has observed that doves having diseased thymus glands have a marked tendency to produce eggs with defective shells and that the disorder can readily be corrected by thymus feeding.

More recently Asher and his collaborators[11] have contributed extensive observations on the influence of an aqueous *thymus extract* which has produced significant acceleration of growth and development. It overcame the loss of weight in rats subjected to vitamin lack and caused hypertrophy of the gonads.

Recently extensive studies have been reported by Rowntree[117] who adds to a review of the preceding literature an account of the work done by himself and collaborators with a thymus preparation evolved by Hanson. The material is an acid-aqueous extract of the neck thymus of young calves. Injections of this extract led to augmentation of weight, more frequent breeding, and production of larger litters of heavier-than-normal offspring. When the treatment was continued through several generations a cumulative effect was seen, each generation showing successively greater acceleration in growth and development as well as sexual precocity. In a subsequent publication Einhorn and Rowntree[37] have reported that thymectomy in succeeding generations has an effect the reverse of that of the thymus extract; there occurred a retardation of development which, however, was spontaneously normalized after seventy days of age. Subsequently these reported effects of thymus extract and of thymectomy have failed of confirmation at the hands of other investigators.

Hypertrophy of the thymus in infancy is a clinical condition encountered frequently in some parts of the world but rarely in others. This may lead to mechanical interference with respiration and has been reported to be associated with abnormal vulnerability of the subjects to anesthesia and trauma. In the field of pediatrics an extensive and somewhat controversial literature on the subject exists. What significance, if any, such manifestations may have in relation to the hormone physiology of the thymus is not evident.

The total weight of the data now available suggests that the thymus has a significant influence upon growth and development and upon sexual maturity but that under favorable environmental conditions the individual is able to dispense with the thymic function without significant detriment to health. Whether the phenomena reported indicate the secretion of a true thymus hormone or whether the relationships are mediated in other ways is by no means certain.

OTHER HORMONES

The *pancreas* by virtue of its contained islands of Langerhans is an important endocrine organ but since the hormone relationships are intimately bound up with carbohydrate metabolism they are treated in the section devoted to that subject (Chapter LI).

The motor and secretory *digestive functions* are likewise in considerable measure subject to hormone control and discussion of the various hormones involved will be found in the chapters devoted to digestion.

In addition to the hormones produced by the various endocrine glands, researches of recent years have disclosed also the existence of what might be designated as special *tissue hormones.* Two are involved in the mediation of nervous impulses and are discussed in connection with the physiology of the autonomic nervous system. They are *acetylcholine* and *sympathin.*

PART VIII

THE DISTRIBUTION AND REGULATION OF WATER IN THE BODY

By Magnus I. Gregersen

CHAPTER LXXVIII

DISTRIBUTION OF WATER

Water is by far the largest single constituent of the body. Claude Bernard endeavored to calculate the proportion of water in the human body by comparing weights of Egyptian mummies with the weights of living individuals of the same size and shape, but his figures (90 per cent) are too high for the reason that prolonged desiccation is attended also by the loss of solid substances. Actual measurements have been made by drying the tissues until there is no further loss in weight. At a temperature of 100-105° C. there is no charring of the tissues and probably very little loss of anything but water. Using this method, Bischoff in 1863 determined the water content of a fresh corpse (executed criminal). His values are tabulated in Table CIX.

Table CIX

(From Siebeck[119])

Body	70 Kg.	Water Content 59% = 41.0 liters
Muscles	30 Kg. = 42% of B.W.	Water Content 76% = 22.8 liters
Fatty Tissues	13 Kg. = 18% of B.W.	Water Content 30% = 3.8 liters
Skeleton	11 Kg. = 16% of B.W.	Water Content 22% = 2.4 liters

From this and subsequent investigations on man and animals, Skelton[120] has compiled results which show that corresponding organs in different species contain approximately equivalent proportions of water (Table CX). Warm-

Table CX

Percentage of Water in Organs in Relation to Their Weight (From Skelton[120])

ORGANS	MAN	RAT	DOG	CAT	RABBIT
Skin	72.03	77.1	58.9	68.3	71.4
Muscles	75.67	76.2	73.5	74.5	75.08

Intestine	74.54	76.36	75.4	78.3	78.4
Entire body	63	65.3	65.7	64.2	68.8

blooded animals seem to have a general similarity both in the total percentage of water and in its anatomical distribution. Nevertheless, the percentage of water in the body may vary considerably among individuals of the same species. It is affected by the quantity of adipose tissue present, since fat is laid down with relatively little water, as illustrated by Bischoff's figures. It varies also with age, gradually decreasing after the first six months. In addition, there are numerous other factors about which our knowledge is limited (diet, endocrines, etc.) that undoubtedly modify the percentage of water under so-called normal conditions. Table CXI shows that the percentage weights of the

TABLE CXI

PERCENTAGE WEIGHT OF ORGANS IN RELATION TO BODY WEIGHT (FROM SKELTON[120])

ORGANS	MAN	RAT	DOG	CAT	RABBIT
Skin	18	18.01	16.11	13.94	13.2

different organs in relation to total body weight are essentially the same for man, dog, rabbit, cat and rat; and Table CXII gives the actual amount of water located in various organs and tissues of the body. By far the largest amount is found in the skeletal muscles and skin. This feature is important in connection with the functions of these two tissues as storehouses for water.

TABLE CXII

DISTRIBUTION OF WATER TO VARIOUS ORGANS AS COMPUTED FROM VALUES SET FORTH IN TABLES CX AND CXI WHEN BODY WEIGHTS ARE: MAN, 65 KG.; RAT, 450 GM.; DOG, 4 KG.; CAT, 2 KG.; RABBIT, 2.5 KG. (FROM SKELTON[120])

O. W. indicates weight of organ in grams; G. W., grams of water in the organ.

The desiccation method for determining the water content of the body has the serious drawback that the determination itself constitutes a terminal experiment, and recent years have therefore seen several attempts to devise techniques that can be utilized in the intact animal and in man. Under appropriate conditions the total body water may be calculated from changes in the concentration of serum electrolytes brought about by the administration of a large quantity of salt or water.[42, 59, 65, 81] According to Painter's recently published work,[103] total body water can also be determined, at least in the dog, with urea or sulfanilamide, for she finds that the body water available for the solution of either of these two substances is the same, within experimental error, as the total body water determined by subsequent desiccation. Incidentally, her observations confirm the now generally accepted conclusion that the amount of "bound water" in the body is relatively insignificant. (See footnote, page 1085.)

When the total amount of body water is altered by adding or withdrawing fluid through the blood stream, all tissues are not affected equally. The capacity of various tissues to take in or give up fluid varies to a considerable degree and is influenced by associated changes in the electrolyte balance. Engels[26] observed that when he gave large intravenous injections of physiological salt solution to dogs, all the tissues except the bone became more watery; the muscles took up most of the injected fluid (67 per cent). His results, however, are open to the criticism that no control observations were made on the injected animals themselves.

More direct evidence is provided by Skelton's experiments on cats in which samples were taken from corresponding tissues of the same animal before and after it was bled or given an intravenous injection of one of several solutions. After severe hemorrhage (15 ml. per kg. body weight), the blood became more watery at the expense of all other tissues examined. Table CXIII shows the pro-

TABLE CXIII

SOURCE OF FLUID ENTERING BLOOD STREAM EXPRESSED IN PERCENTAGE OF AMOUNT COMING FROM VARIOUS TISSUES (FROM SKELTON[120])

CAT	SKIN	MUSCLE	LIVER	INTESTINE	SPLEEN

5.	30	45.2	10.4	0.74	0.72

portion of the total water which entered the blood from various tissues, and Table CXIV the amount of fluid given up per 100 Gm. of tissue. In his cats 1 and 2 which had no previous treatment, the muscles supplied somewhat more fluid than the skin; but in animals 3 and 4 which had been given no food or fluid for 32 and 72 hours, respectively, the skin was by far the most important source of fluid, and also gave up more water per 100 Gm. of tissue than any other organ. Although the muscles contain two and one-half times as much water as the skin, the latter competes with the muscles as a storehouse for water by virtue of the fact that it may undergo much larger changes in its percentage of water.

Skelton's results with injections of water (25 ml. per kilogram) and hypo-, iso- and hypertonic solutions of sodium and calcium chloride (20 ml. per kg.) are included in Table CXV. We see that in the case of water and hypotonic sodium chloride solution, the muscles and the liver took up most of the water, whereas with isotonic and hypertonic sodium chloride the fluid went mainly to the skin, the muscles either undergoing no change or actually losing water. Padtberg[102] believed that the skin has a special function in relation to the storage of sodium chloride. After intravenous injections of this salt, as much as 77 per cent of the amount retained was found in the skin; and when animals were kept on a chloride-poor diet, the skin provided from 60 to 90 per cent of the total chloride lost from the body. There is also evidence that the skin can store salt, at least temporarily, with less than enough water to dilute it to isotonicity. If large amounts of salt are taken by mouth, only a portion is excreted at once; the location of the retained chloride is indicated by the edema of the skin which is produced when a large amount of water alone is subsequently ingested. Sodium chloride not only directs the water to the skin, but tends to hold it in the body.

TABLE CXIV

AMOUNT OF FLUID GIVEN UP BY 100 GM. OF TISSUE FOLLOWING HEMORRHAGE (FROM SKELTON[120])

CAT	SKIN	MUSCLE	LIVER	INTESTINE	SPLEEN
1.	1.2	0.6	2.2	1.9	1
2.	1.2	0.4	2	1.3	0.6
Average	1.2	0.5	2.1	1.6	0.8
3.	3.2	0.4	3.2	0.9	3.3
4.	4	0.39	3.2	0.7	2.17
Average	3.6	0.4	3.2	0.8	2.73
5.	2.1	0.9	3.2	1.75	0.25

The difference observed by Skelton in the effects of sodium and calcium chloride in corresponding concentrations (Table CXV) is referable to the fact that calcium is much less diffusible than sodium. This is shown by the more persistent hydremia and by the movement of fluid from all the tissues into the blood when the hypertonic (2.4 per cent) solution was injected. In the latter case, the skin was again the most important source of fluid.

The general implication of these experiments is that the water content of the blood and other vital organs is to a large extent preserved at the expense of changes in the fluid content of the muscles and the skin. Other tissues, such as the liver and intestines, also play an important role, especially in taking care of sudden changes; but because of the relatively smaller mass of these organs in comparison with muscle and skin, they handle correspondingly smaller quantities of fluid.

The capacity of various organs to function as fluid reservoirs appears to be conditioned by the amount of loose connective tissue which they contain. As described above, it was from the skin, in which this form of histological structure with large intercellular spaces is particularly prominent, that Skelton found the largest fluid loss per 100 grams of tissue after injection of hypertonic $CaCl_2$. Organs consisting mainly of parenchyma are said to show

Under A are listed the percentages of the injected fluid remaining in the blood stream or absorbed by the various tissues at the end of thirty minutes; under B, the grams of fluid taken up or lost (—) by 100 Gm. of tissue.

The results with distilled water are an average of six experiments: with 0.45% sodium chloride, 8; 0.9% sodium chloride, 8; 1.8% sodium chloride, 6; 0.6% calcium chloride, 6; 1.2% calcium chloride, 6; 2.4% calcium chloride, 4.

no appreciable loss of water in severe dehydration.* From these and other observations the belief has arisen that the intercellular spaces serve as a reservoir of fluid for sustaining the plasma volume.[38]

There can be no doubt that this concept is correct, for in dehydration, for example, the actual decrease in volume of the plasma constitutes but a small fraction of the total loss in the body. As the body gives up water to the external environment, it also draws upon the fluid stores in the adjacent interstitial spaces. But this does not mean that the plasma volume is maintained at a constant level in the face of a large depletion of the total body water. On the contrary, it has been the experience of the writer, based on results obtained with suitable methods for estimating changes in volume of the body fluids (see pages 1067-1071), that in dehydration the per cent shrinkage in the plasma volume is considerably greater than that observed in the interstitial fluid.[52] This is illustrated by Table CXVI showing the results of a typical ex-

TABLE CXVI

SHOWING THE EFFECTS IN THE SAME DOG OF TWO PERIODS OF FOOD AND WATER DEPRIVATION

periment on a dog subjected to eleven days' water deprivation. It should be noted that this experiment is a glaring example of circumstances in which one would arrive at an entirely erroneous conclusion by assuming that relative changes in plasma volume can always be estimated from the change in plasma protein concentration.

The various studies on the anatomical distribution of water and its relation to the electrolyte exchange have led to a very useful concept of the partition of the body fluids based on function. This is shown diagrammatically in Fig. 365. As a distinct compartment we have the water contained in the vascular system, through which fluid is being circulated rapidly under pressure maintained by the action of the heart. At the bottom lies the intracellular fluid in which the living processes occur. Separating these two is the intercellular or interstitial fluid which surrounds the cells and constitutes the internal environment of the organism. Water enters the system through the small and large intestines and leaves by way of the lungs, skin and kidneys. A small amount is also excreted in the feces. The total water content of the system is determined by the mechanisms which control the passage of fluid through these channels. Since fluid passes in and out of the body only through the plasma compartment, the interstitial and intracellular compartments depend entirely upon the plasma for their supply.

*Kudo's[74] studies on the loss of weight of selected organs in the rat after severe dehydration and inanition do not support these statements. His animals, however, were dehydrated and starved until they lost approximately one-third of their weight and it may well be that this condition is too extreme to display any selective loss of the interstitial fluids.

The problem of water balance, therefore, presents two main aspects which are closely related: 1, the exchange between plasma and the outside; i.e., the total water exchange of the body; 2, the exchange between plasma and the interstitial and intracellular compartments. Inasmuch as the walls of the fluid compartments are elastic, the mechanisms which control the volume of water in the entire body and its separate compartments are complicated and must be delicately balanced. These mechanisms are our chief concern, but before discussing them it is advisable to gain some idea of the composition of the body fluids and the actual amount of water distributed in each of the three compartments.

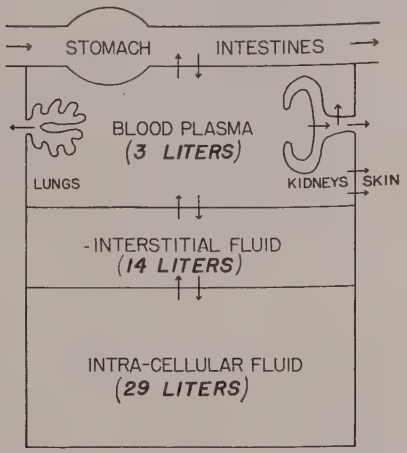

Fig. 365.—Gamble's diagrammatic illustration of the three fluid compartments. The figures in parentheses have been inserted by the author to show the volume of water in each compartment of a subject weighing 70 kg. whose total water content is assumed to be 46 liters (two-thirds of the body weight). (Modified from Gamble.[39])

COMPOSITION OF FLUID IN THE VASCULAR, INTERSTITIAL AND INTRACELLULAR COMPARTMENTS

Detailed information on the composition of the various body fluids may be found in textbooks of biochemistry. For the purposes of the present discussion, it is sufficient to consider diagrammatically the ionic concentrations of the important constituents in the three fluid compartments, as in Fig. 366.

The composition of the vascular compartment is given by the analysis of serum. The erythrocytes are not included, for they form a rather specialized part of the intracellular compartment. The composition of interstitial fluid is represented approximately by the second and third diagrams, constructed from analyses of lymph and cerebrospinal fluid, which are believed to have nearly the same composition as true interstitial fluid. The latter does not under normal conditions accumulate in sufficient quantity to be collected for analysis, but Maurer[93] has succeeded in obtaining small amounts of true extracellular muscle fluid from the frog. The composition of intracellular fluid is also a matter of some uncertainty, since it is impossible to remove the interstitial fluid dispersed among the cells; but the important chemical features of the intracellular compartment are shown by the analysis of muscle. The assumption which apparently best fits experimental facts is that the intracellular fluid contains only a small amount of sodium and no chloride.[61]

From Fig. 366 it is evident that except for the difference in protein content the plasma and interstitial fluids are practically identical. In both, the base is almost entirely made up of sodium, the acid largely of chloride and bicarbonate. The barrier which separates the two compartments is therefore

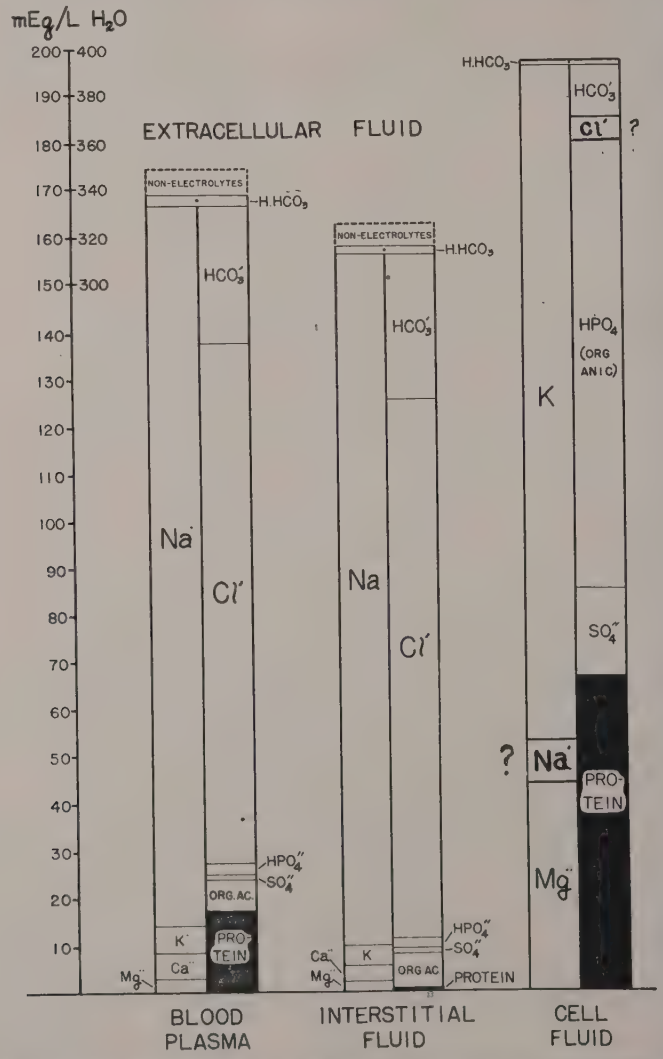

Fig. 366.—Diagram showing the chief chemical constituents of the three fluid compartments. The height of the left half of each column indicates the total concentration of cations, that of the right half, the concentration of anions. Both are expressed in milliequivalents per liter of water. Note that the chloride and sodium values in cell fluid are questioned. It is probable that at least in muscle the intracellular phase contains some sodium but no chloride. (Modified from Gamble.[87])

permeable to all constituents except the protein, a situation which gives rise to a slightly higher chloride and lower sodium concentration in the interstitial fluid than in the plasma (Gibbs-Donnan effect).

The intracellular fluid presents a very different picture. Here we find potassium as the predominant base and no chloride among the anions, showing that the barrier between the interstitial and intracellular compartments is endowed with a high degree of selective impermeability. This is further illustrated by the unequal distribution of phosphate. From the point of view of chemical structure, therefore, intracellular fluids are entirely different from the extracellular fluids, whether in plasma or intercellular spaces.

VOLUME OF FLUID IN THE VASCULAR, INTERSTITIAL AND INTRACELLULAR COMPARTMENTS

The Vascular or Plasma Compartment.—Of the three fluid compartments, the vascular is the smallest but in many respects the most important. It is the link between the internal and external environments, the sole channel of exchange for all substances which reach the cells and are carried away from them. By virtue of the fact that it circulates rapidly through every portion of the body, it endows the tissue fluids bathing the cells with the same constancy of composition which in the plasma itself is jealously guarded by innumerable mechanisms. In order to carry out this function effectively, the plasma must maintain its volume as well as its composition. More than that, the volume, through its effect upon capillary pressure, is a potent factor in deciding the direction of fluid exchange between plasma and tissue fluid. The body keeps the plasma volume constant with great persistence, a fact which suggests that changes in the plasma volume are in themselves responsible for setting in operation the mechanisms which exist for its regulation. Such an arrangement presents obvious advantages to the organism, since any influence of the external environment upon the fluid balance is first made known in the vascular compartment.

The plasma volume may be determined by injecting a known amount of some nontoxic, nondiffusible foreign substance intravenously and measuring the extent to which it is diluted when thoroughly mixed with the circulating blood. Among the substances which have been used for this purpose may be mentioned gum acacia, foreign serum, hemoglobin and a number of vital dyes (vital red, brilliant vital red, congo red, trypan blue, trypan red, T-1824 and others). The aim has been to select a substance which escapes very slowly from the blood stream, which is not taken up by the red cells, is soluble and stable in the plasma, and which can be determined accurately and conveniently in plasma or serum samples. For the last reason in particular, dyes have been most popular since their concentrations can be estimated colorimetrically. The use of dyes for measuring plasma volume was introduced in 1915 by Keith, Rowntree and Geraghty.[71] For description and criticisms of their technique and of the many subsequent modifications of the dye-dilution method, the reader is referred to the articles by Erlanger,[27] H. P. Smith,[123-125] Seyderhelm and Lampe,[115] Griesbach[56] and Gregersen, et al.[44, 49, 50, 54, 55] Of the mass of data which has accumulated, so much conflicts on grounds purely technical that it is desirable to consider briefly some of the chief sources of error in the method.

The determination of the concentration of dye in a sample of plasma or serum may be complicated by the fact that the solvent itself is not water clear or colorless. Keith, Rown-

tree and Geraghty[71] attempted to cancel natural plasma color by reading the unknown (dye-stained plasma obtained after the dye injection) against a standard prepared by adding a measured amount of the dye solution which was injected to a sample of control plasma (taken just before injection). Both samples were diluted to the same extent to maintain equal concentrations of the original plasma constituents. Even this precaution does not insure a correct determination in a simple colorimeter unless the dye concentrations happen to be identical in the two samples, i.e., unless the fields match when the plungers are set at the same height (R = 100). If this condition is not fulfilled and the circulating plasma is highly colored with dye left over from a previous determination (residual dye), the error in estimating the increase in plasma color resulting from a single injection may be very large (30 per cent). The nature of this difficulty is seen from the equation:[123]

$$\frac{R_3}{100} = \frac{R_1 + R_3}{R_2 + 100}$$

in which R_1 is the residual dye, R_3 the increase in dye concentration of the plasma caused by the injection, and R_2 the actual colorimetric reading. This shows that the value R_3 which must be used in calculating the plasma volume is not the same as the actual colorimetric reading R_2 unless R_1 is equal to zero or unless R_2 is equal to 100. Furthermore, it shows that the discrepancy between R_2 and R_3 depends upon whether R_2 is higher or lower than 100. Therefore, the estimated plasma volume may be too high or too low depending upon the relative concentration of the standard and unknown. This is shown by the following experiment, the results of which are presented in Table CXVII.

TABLE CXVII

REPEATED DETERMINATIONS OF PLASMA VOLUME (DOG) WITH THE KEITH-ROWNTREE METHOD SHOWING THE RESULTS OBTAINED WITH STANDARDS OF DIFFERENT STRENGTHS

STANDARD (DILUTION OF ORIGINAL DYE SOLUTION)	PLASMA VOLUME IN ML.				RATIO OF UNKNOWN / STANDARD
	1ST	2ND	3RD	4TH	
1-300	925	925	930	910	R = 100
1-200	—	780	710	670	R > 100
1-400	—	1075	1115	1150	R < 100

The plasma volume of the dog was determined four times in the course of a few hours by the dye method as described by Keith, Rowntree and Geraghty. In each case, the unknown was read against *three* standards of different strengths, and the plasma volume calculated from each of these readings. It is evident that the same result was obtained only when the unknown was read against a standard of equal strength (R = 100). As the residual dye concentration increased after each injection, the other results were progressively higher or lower than the true volume, depending upon which standard was used. Thus one may account for the inconsistent values reported by certain investigators who have used the Keith-Rowntree technique for repeated determinations.[76]

Theoretically, the compensating colorimeter should eliminate the difficulties with residual dye and natural plasma color. The important feature of this instrument is that optical symmetry is maintained no matter how different the standard and unknown happen to be; but for reasons which are not clearly understood, this colorimeter fails to yield dependable results. Furthermore, it cannot be used if the plasma samples show any lipemia or if samples are hemolyzed. It should be noted also that in analyses with the compensating colorimeter, a number of investigators have introduced systematic errors into their determinations by comparing the unknown with standards made up in water instead of in plasma. The dyes commonly used for estimating plasma volume all show definite changes in their spectral absorption when either salt or protein (plasma) is added to the water solution. As a rule, these dyes have a greater color intensity in water than in plasma, and therefore if the dye plasma is read against a water standard, the calculated dye concentration will be too low and the plasma volume correspondingly too high.[44]

By using a spectrophotometer these difficulties can be readily overcome. With this instrument direct comparison of the unknown with a standard is eliminated. The dye con-

centration is measured in terms of optical density (the fraction of light absorbed by the solution at some particular wave length of light), which is directly proportional to the concentration of the dye; and absorption by the solvent itself is cancelled by simply reading the unknown serum against the control. Consequently, with the spectrophotometer one can determine directly the increase in plasma-dye concentration resulting from a single dye injection, regardless of whether or not the plasma contains residual dye. Another important advantage of spectrophotometry is that errors from hemolysis can be eliminated by the simple expedient of using a blue dye which has its peak of absorption in the red end of the spectrum where the absorption by hemoglobin is relatively insignificant. For this reason, and because it disappears slowly from the plasma, the blue dye T-1824 is quite satisfactory.

The dye-dilution method is based on the assumption that the dye is distributed solely in the plasma, and that none of it is taken up by the red blood cells. Tests have shown that T-1824 fulfills the latter requirement.[54] Much of the work done with the dye method has also been based on the assumption that the dye is uniformly distributed in the circulation in from four to six minutes. Time-concentration curves obtained on human beings, dogs, and cats show that uniform distribution usually takes longer and may, in special instances, require thirty to forty minutes. Since appreciable quantities of dye may in the meantime escape from the blood stream, it is impossible to calculate the volume accurately from any one sample obtained after mixing is complete. A satisfactory solution is shown in Fig. 367. The "disappearance" portion of the time-concentration curve is projected back to the time when dye was injected. This gives the dye concentration which would be obtained if mixing were instantaneous, that is if mixing occurred before any dye had escaped from the blood stream. With this technique, the determination of volume is independent of the circulation rate.

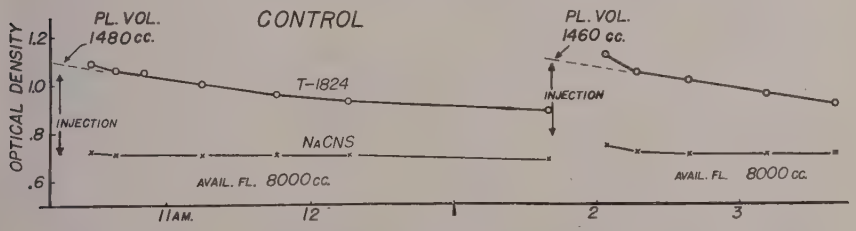

Fig. 367.—Time-concentration curves of the blue dye T-1824 and of sodium thiocyanate (see text).

During the period required for uniform distribution of the dye (twenty minutes or more) some escapes from the blood stream. By projecting the disappearance curve back to the time of injection one may correct for this loss and estimate the concentration of dye (expressed in terms of optical density) which would exist if uniform distribution occured immediately. The plasma volume is calculated from this value by the equation:

$$\text{Plasma volume in ml.} = \frac{\text{Conc. of standard dye sol. x ml. injected}}{\text{Conc. in plasma}}.$$

Sodium thiocyanate is usually eliminated so slowly from the body that the plasma concentration remains practically the same for several hours after uniform distribution has occurred. Therefore no correction need be made for disappearance, as in the case of T-1824. The volume of fluid available for dilution of thiocyanate is approximately equal to the volume of extracellular fluid (plasma plus interstitial fluid).[55]

It is incorrect to assume, as many have done, that the total blood volume can be calculated from the plasma volume and the hematocrit. Comparisons of total blood volumes as estimated, (1) from the dye method (which measures only the plasma volume) and the hematocrit, and, (2) from the carbon monoxide method (which measures the total volume of red cells in circulation) and hematocrit, show a discrepancy of 25-30 per cent.[127] Since the dye method gives the higher value, Smith, Arnold and Whipple[126] suggested that blood in the capillary bed is relatively richer in plasma than the blood in the large vessels. Direct observation on the flow of blood through smaller vessels has indeed revealed that this is the case. The cells move through these vessels in an axial stream which has a higher linear velocity than the surrounding zone of clear plasma. Fåhraeus[28] has demonstrated that the same phenomenon occurs in vitro with blood flowing through capillary tubes of small diameter (0.1 mm. or less), and maintains that it is a characteristic of all suspensions flowing through capillary tubes of small bore.

From the results of numerous investigations, it appears that the plasma volume per unit body weight is far from constant even within a selected group of normal individuals. Keith, Rowntree and Geraghty,[71] for example, found normal values between 42 and 56 ml. per kilogram body weight; and the writer, using the blue dye T-1824, has obtained results on normal medical students ranging from 37.6 to 58.5 ml. per kilogram. Similar variations have been reported by others, regardless of the method used. It is interesting to observe, in contrast to these findings, that repeated determinations on the *same* subject under similar conditions show a fairly constant plasma volume. There can be no doubt that individual differences of considerable magnitude actually exist. It is known that obese subjects have less plasma per kilogram body weight than normal persons, but there are undoubtedly a number of structural and physiological differences among individuals which play an important part. Changes with age appear only during the first two to three years of life. The volume in proportion to body weight is highest at six months, and then gradually falls until in the third or fourth year it is equal to the value for adults. Rowntree[113] has suggested that the blood and plasma volumes should be expressed in terms of body surface. Although the plasma volume does seem to be somewhat more closely related to body surface than to body weight, it is doubtful if much significance can be attached to single determinations unless they fall well outside the range of normal values.

For the purposes of the present discussion it is sufficient to bear in mind that the average plasma volume estimated from a large number of determinations is approximately 45 ml. per kilogram body weight. The vascular compartment of a man weighing 70 kilograms would therefore contain about 3,200 ml. of plasma, or, correcting for the plasma proteins, about 3,000 ml. of water (see Fig. 365).

The Interstitial Fluid Compartment.—The volume of the interstitial fluid is not subject to separate measurement, but it can be calculated by subtracting the volume of fluid in the vascular compartment from the total volume of extracellular fluid. The problem is, therefore, principally one of estimating the volume of the latter.

If there is no chloride in the intracellular compartment (and this seems to be the case at least in muscle), then the total extracellular fluid can be calculated from the concentrations of chloride in the serum and interstitial fluid and from the total chloride content of the body. In this manner Harrison, Darrow and Yannet[59, 104] have estimated that the extracellular water in the rabbit and the dog is equal to between 25 and 30 per cent of the body weight. Making the same calculations from sodium analyses the results are approximately 10 per cent higher. In either case the values are undoubtedly a little high since the distribution of electrolytes in muscle is probably not duplicated in certain glandular structures, the cells of which must, by the very nature of the secretions they produce, contain both sodium and chloride. Manery's[88] studies on the distribution in injected radioactive sodium and chloride indicate that in a number of tissues, particularly the brain, a considerable proportion of both sodium and chloride is intracellular; and furthermore, Amberson and his co-workers,[4] in their total plasmapheresis experiments with chloride-free perfusion fluid, found that chloride was retained by the stomach, spleen, salivary glands, and especially by the central nervous system.

A convenient and simple method of estimating changes in the volume of extracellular fluid in intact animals and in man was suggested by Crandall[19] on the basis of his studies of the bodily distribution of sodium thiocyanate. His results indicated that the fluid available for dilution of thiocyanate is approximately the same as the volume of extracellular fluid. This inference is supported by the observations of Lavietes, Bourdillon and Klinghoffer,[80]

that the substances sodium chloride, sucrose, and sulfate are also distributed through nearly the same volume of body fluid as sodium thiocyanate. The fact that neither sucrose nor sulfate enters the red blood cells is presumptive evidence that they also do not enter other cells in the body. Although thiocyanate enters the erythrocytes, its penetrability into other cells in the body seems to be no greater than that of sulfate or sucrose since, as we have said, all three yield the same values for "available fluid." It is excreted so slowly by the kidney that practically none of it is lost during the forty to fifty minutes required for uniform distribution. The plasma level is constant thereafter for several hours (see Fig. 367). Complete removal from the body takes from five to eight days.

It should be pointed out that the question which was raised in connection with the assumption that the extracellular fluid volume is equal to the total sodium or chloride space also applies to thiocyanate; namely, that this substance is secreted by various glands and therefore the fluid available for its solution probably includes some intracellular water. How important this is remains to be seen. After all, we have no absolute assurance that the extracellular space in the strict anatomical sense is identical with that which functions as such. Another characteristic of thiocyanate, which however would tend to give values for the "available fluid" volume which are lower than the true extracellular fluid, is that this substance is apparently not distributed in a 1:1 ratio between plasma and interstitial fluid. Lavietes[79] has observed that at equilibrium the concentration of thiocyanate is slightly higher in the plasma than in a perfusate because thiocyanate has an affinity for the plasma lipids. In this respect the more laborious bromide technique developed and employed by Brodie and his co-workers[14] is preferable to the thiocyanate method and, as one would expect, the estimated volume of extracellular fluid is somewhat higher. Furthermore, the experimental evidence shows that the bromide space agrees closely with the chloride space.

According to the results obtained with these techniques the extracellular fluid volume in man varies considerably from individual to individual, but the average is about 25 per cent of the body weight. Accepting this as a normal average and subtracting the volume of plasma (4.5 per cent of the body weight), we may conclude that the interstitial compartment is 18 to 20 per cent of the body weight. The volume of the interstitial fluid in a normal subject weighing 70 kilograms is therefore equal to about 14 liters. This value has been inserted in Fig. 365.

Intracellular Fluid Compartment.—Since we have no method for determining separately the volume of fluid in the intracellular phase, we can only calculate it from estimated values for the total body water and from the volume of extracellular fluid (plasma plus interstitial fluid). Assuming that the body is two-thirds water, the total water content of a normal subject weighing 70 kilograms is equal to 46 liters. Since the vascular and interstitial compartments together contain approximately 17 liters, we have 29 liters to be accounted for in the intracellular phase.

CHAPTER LXXIX

TOTAL WATER BALANCE; THIRST, DEHYDRATION AND WATER INTOXICATION

The total water content of the body is dependent upon the rate of exchange through the various channels shown in Fig. 365. Water is supplied in the form of fluid taken as such, but a surprising proportion also enters the body as an integral part of the food. Fruits and vegetables as a rule contain over 90 per cent water, and the so-called solid foods between 60 and 85 per cent. It is difficult indeed to find a constituent of the diet which contains less than 50 per cent water. When food is burned in the body, a certain amount of water is also liberated as the water of oxidation. An ordinary mixed diet yields about 300 ml. of water from this source; 100 grams each of fat, starch and protein yield, respectively, 107.1, 55.5 and 41.3 grams of water of oxidation.

Fluid taken by mouth does not become an integral part of the body until it has been absorbed from the lumen of the gut. This process, which occurs mainly in the small intestine, is preceded by the establishment of osmotic equilibrium between the fluid and the blood, and the rate at which absorption takes place is therefore determined somewhat by the concentration of the ingested fluid. In the case of hypertonic solutions, absorption is retarded by the initial diffusion of water from the blood. The rate at which the contents of the intestines pass into the blood stream also depends upon the diffusibility of the dissolved substances. Sodium chloride, for example, enters the blood with great rapidity, but magnesium sulfate, to which the wall of the intestine is practically impermeable, prevents absorption. This accounts for the purgative action of Epsom salts of which magnesium sulfate is the chief constituent.

Large quantities of fluid are secreted into the mouth, stomach and intestine in the course of digestion. Normally this fluid is not permanently lost from the body, but is reabsorbed as digestion proceeds. It has been estimated that the exchange is between 3 and 10 liters per day. Table CXVIII indicates the relative amounts which are secreted by the various digestive organs. With a turnover of this magnitude, greater than the plasma volume, it is not difficult to visualize the effect of continued loss of digestive secretions, such as occurs in persistent vomiting or diarrhea.

The amount of water normally lost through the kidneys is dependent upon many factors, chiefly upon the available supply of body water. Generally speaking, it bears an inverse relation to the amount vaporized through the skin and respiratory tract. Ordinarily, the renal and extrarenal channels discharge approximately equivalent amounts of water, about 1 liter each a day. In the tropics, urine secretion may be reduced to a minimum, while the greater part of the 10 or 12 liters of water drunk per day is lost through the skin. Under these conditions a considerable amount of sodium chloride is also excreted by the sweat glands, thus reducing the volume of water required by the kidneys for the excretion of salt. The normal variations in the urine output are indicated in Table CXVIII.

Since the quantity of water ingested is normally in excess of the bodily needs, the kidneys usually function as a spillway for the water not dissipated through the extrarenal channels; but when the water supply is meager, the kidney excretes salts and waste products in high concentration. Recent evidence indicates that the water output in the urine is regulated by the posterior pituitary gland. This question will be considered further in the chapter on urine secretion.

Except for a small amount of water excreted in the feces, extrarenal loss of fluid occurs through the lungs and skin. Loss through the lungs is determined by the ventilation and by the difference in vapor tension between the inspired and expired air. The expired air is not, however, saturated with water vapor as might be supposed. Direct measurement on alveolar air shows that even in the lungs the vapor tension is always somewhat lower (1.5 to 2.0 mm. of Hg) than the saturation point at the body temperature. In dogs, which are largely devoid of sweat glands, the evaporation of water from the mouth, lungs and respiratory passages can be increased by panting, an important means of dissipating heat. Panting is initiated mainly by a rise in the skin temperature but may also be facilitated by a conditioned reflex.

TABLE CXVIII

RATES OF TURN-OVER OF WATER BY VARIOUS ORGANS IN A 70-KILO HUMAN INDIVIDUAL, IN MILLILITERS PER 24 HOURS (From Adolph[2])

ORGANS	MINIMUM	LIBERAL
Salivary glands	500	1,500
Stomach	1,000	2,400
Intestinal wall	700	3,000
Pancreas	700	1,000
Liver (bile)	100	400
Lymph	700	1,500
Total recovered by body	3,700	9,800
Kidneys	600	2,000
Colon (feces)	50	200
Skin (insensible loss)	350	700
Sweat glands	50	4,000
Mammary glands	0	900
Total lost from body	1,050	7,800
Total turn-over	4,750	17,600

The loss of water through the skin is partly an insensible cutaneous loss and partly a visible secretion of sweat. The latter is negligible under basal conditions at ordinary room temperature but serves as an emergency mechanism to provide water for evaporation in case of need during exercise, exposure to high temperature and in fever. In extreme conditions the amount of sweat secreted may be very large (1 to 2 liters per hour in a hot bath).

As shown in Table CXVIII the insensible cutaneous loss is about 300 to 700 ml. per day. That the sweat glands contribute an insignificant part of this amount is indicated by the fact that a similar quantity of water is liberated from the skin of individuals who have no sweat glands. The volume of water lost as insensible perspiration bears a remarkably constant relationship to the metabolic rate.[25] Thus, conditions which increase the metabolic rate, such as exercise, the taking of food or hyperthyroidism, cause a proportional aug-

mentation of the insensible water loss. Dehydration and water drinking have no significant effect except when pushed to extremes. Serious disturbances of the body fluids do, however, influence the insensible perspiration, as do changes in skin temperature and changes in the blood flow through cutaneous areas.

We may then summarize the above discussion as follows: The respiratory and insensible cutaneous loss of water goes on continuously and at an approximately constant rate. The loss through the kidneys and sweat glands, however, fluctuates greatly. Conservation of water in time of need is effected principally through the reduction of excretion by the latter channels. Under normal circumstances the intake of water exceeds the requirements, causing the kidneys to excrete more water than is essential for the elimination of solids.

Regulation of the Water Intake: Thirst.—Although the water intake undergoes large variations in the course of natural existence, the water balance is maintained within surprisingly narrow limits, as indicated by the constancy of the body weight. In a subject studied for forty-nine days, Atwater and Benedict found that the water intake fluctuated from 880 to 2,440 ml. of water per day, the average consumption being 2,290 ml. per day. Under conditions of moderate work, the intake varied from 2,225 to 4,550 ml., an average for 66 days of 3,700 ml. per day. The report has been made by Hunt that in India a person may drink as much as 13 liters per day. These facts presuppose the existence of some mechanism for the regulation of the intake, adjusting it to the bodily needs. Dehydration is accompanied by a number of visible changes—dryness of the skin, shrinkage of subcutaneous tissue, decreased deformability of the skin and reduction in the urine flow. But these are of little concern to the dehydrated individual in comparison with the dry mouth and sensation of thirst which claim all his attention. This sensation is the warning signal indicating the need for increasing the water content of the body, and as such has great practical significance.

The question of the origin of the sensation of thirst has been a subject of controversy among physiologists for more than three-quarters of a century. One group has held that the sensation is of diffuse origin, since it is associated with conditions involving a general depletion of the body fluids and since it is abolished directly by intravenous injection of water or salt solution. Those who adhere to this point of view ascribe only slight significance to the local sensation of dryness in the mouth. According to Schiff, dryness of the mouth is merely a secondary phenomenon which . . . "bears no deeper relation to the general sensation than heaviness of the eyelids bears to the general sensation of sleep." The interpretation of various experiments brought forth in support of the theory that thirst is of diffuse origin does not withstand critical examination. Furthermore, the theory leaves one in a quandary as to how the sensation arises. Does it entail the existence of a special system of nerves which are sensitive to changes in the water content of the tissues and which serve to inform the central nervous system of these changes? There is no anatomical basis whatsoever for such an assumption. One might possibly claim that there is a center in the brain sensitive to increases in the concentration of the blood, but the difficulty with this explanation is that thirst is produced in the absence of increased concentration of the blood when the water content of the body is depleted by hemorrhage. There is now a large body of evidence which indicates that the sensation of

thirst is really what it seems to be; namely, a dryness of the mouth and throat. For a discussion of the older literature, the reader is referred to the review by Cannon.[17]

The theory that thirst is of local origin has been championed by Cannon, who in support of his view has drawn liberally upon the testimony of individuals who have suffered extreme thirst. It is a matter of common experience, for example, that thirst may be temporarily relieved by measures which merely serve to moisten the mouth and which do not alter the amount of water in the body itself. McGee,[95] a geologist of wide experience in the southwestern deserts of the United States, reports, "commonly the condition is alleviated by a moderate quantity of water; sometimes fruit acids and other acid substances, exciting a flow of saliva are requisite for relief; and in the practical life of the range, a pebble or nail carried in the mouth is often efficacious. . . ." Anyone who has experienced severe thirst is acutely impressed with the fact that the thirsty man's chief concern is to be relieved of the torment of dryness in his mouth and respiratory tract. That thirst is a local phenomenon is also shown by the fact that "breathing hot air free from moisture, prolonged speaking or singing, the repeated chewing of desiccated food, the inhibitory influence of fear and anxiety on salivary secretions, have all been observed to result in dryness of the buccal and pharyngeal mucous membrane, and in attendant thirst."[17]

The correlation between thirst and a reduced salivary flow was demonstrated by Cannon and has since been confirmed by others. In man, the salivary flow may be tested by measuring the amount of saliva secreted in response to chewing a tasteless gum at a uniform rate, or by breathing through the mouth. In a dog, the duct from one of the submaxillary glands may be exteriorized and the saliva collected in a funnel attached over the fistula. A uniform stimulus is provided by exposing the dog to a warm atmosphere, under which conditions the animal pants at a constant rate; as the mouth becomes dry, the salivary glands are reflexly stimulated to secrete.[45]

If Cannon's theory of thirst is correct, it should be possible to demonstrate that the elimination of the salivary flow, either by tying the salivary ducts or by complete extirpation of the salivary glands, causes thirst and stimulates drinking of water in spite of the absence of bodily dehydration. Montgomery[99] put this question to an experimental test by measuring the daily water intake of dogs before and after extirpation of the submaxillary, sublingual, parotid and infraorbital glands. Contrary to expectation, she found that the animals consumed no more water after the removal of the glands than they did before. It must be remembered, however, that the buccal mucosa is dotted with glands which are capable of secreting a certain amount of fluid. Miss Montgomery collected 8.9 grams per hour from this source in one of her dogs. To make the experiment crucial, the water intake should be tested under experimental conditions which cause drying of the buccal mucosa. This can be accomplished by exposing the animals to an atmosphere warm enough to make them pant. Gregersen and Cannon[48] demonstrated that under these conditions, dogs drank more than twice as much water after tying of the parotid duct and removal of the submaxillary, sublingual and intraorbital glands.

Further evidence of the relation between decreased salivary flow and the appearance of thirst is provided by a study of drinking habits in dogs.[47] Continuous records obtained under normal laboratory conditions show that dogs

rarely drink except when they are fed (Fig. 368); when food is withheld, they drink only about one-fourth of the usual amount. The need for water after meals is explained by the temporary withdrawal of body fluids for the formation of digestive juices. Since these secretions are reabsorbed in the later stages of digestion, the desire for water should also disappear. That this is the case may be shown by withholding water for six or eight hours after a meal and then measuring the water drunk, at which time the dog consumes much less water than it usually drinks during the postprandial period when given water *ad libitum*. The temporary dehydration after meals is reflected also in a marked fall in the salivary flow, a change which has been shown by the writer to occur in both man and the dog. These facts again demonstrate the intimate relation which exists between the state of hydration of the body and the salivary flow.

Since dehydration reduces the quantity of secretion produced all along the digestive tract, the observations which have just been described suggest that an abundant supply of digestive juices would be facilitated by the ingestion of generous quantities of water with meals. Water which is taken with food escapes quickly into the small intestine where it is promptly absorbed, while the food material remains in the stomach. That the water ingested

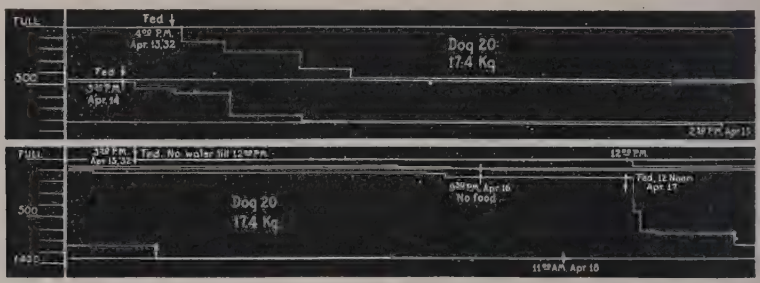

Fig. 368.—Drinking records on a dog. The length of the record covers a period of twelve hours. The upper chart covers a normal control period; it shows that most of the water drunk during twenty-four hours is taken within a few hours after the dog is fed. This is true no matter what time of day food is given. The lower record demonstrates that the postprandial thirst is temporary. On April 15 food was given at 3:30 P.M., but water was withheld until 12:00 midnight. At that time the dog drank only a small amount and consumed scarcely 100 ml. during the next thirty-six hours. The subsequent feeding on April 17 was followed by the usual ingestion of fluid. (From Gregersen.[47])

does not retard the rate of digestion was shown by Hawk and his collaborators.[96] He found that the ingestion of a liter of water, coffee or tea had no effect upon the rate of development of gastric acidity after meals. If cream is added to the tea or coffee, or if chocolate in equivalent quantities is taken, the rate of digestion is definitely retarded. This is in harmony with the observation that fatty foods leave the stomach much less quickly than do carbohydrates or proteins. It therefore seems that the only deleterious effect of taking water with meals is caused by the tendency to swallow food without adequately chewing it; the drinking of water after the food has been swallowed can be looked upon as beneficial in the sense that it provides a larger store of fluid in the body for the formation of digestive juices.

Granted that the immediate cause of thirst is a dryness of the mouth and throat resulting from a diminished output of saliva, it still remains to be shown how this secretion is reduced by dehydration. Under ordinary circumstances, the activity of the salivary glands is entirely determined by stimuli carried to them through the sympathetic and parasympathetic nerves. If these nerves are

cut, secretion ceases.* This suggests the possibility that in dehydration the reflex arc is either interrupted or partially blocked. But according to Morgulis,[100] this is not the case. He states, "In fasting dogs, even in an advanced stage of inanition, the submaxillary gland can be excited to activity through chorda tympani stimulation, the latent period being even shorter than in the normal dog. The saliva thus obtained, though less in amount than normally, showed no qualitative differences. The mechanism of reflex secretion is likewise apparently intact, since an augmented secretion of a clear and watery saliva is called forth by introducing acetic acid into the buccal cavity." Furthermore, he finds that, "The chorda tympani secretory fibers supplying the submaxillary gland retain their excitability to the very last moment of the animal's existence; stimulation

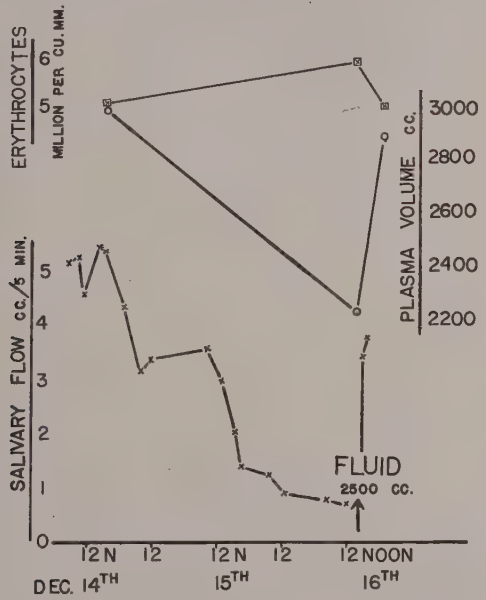

Fig. 369.—Changes in plasma volume and salivary flow produced by two days' water deprivation and the subsequent ingestion at one time of 2500 c.c. (ml.) of fluid. The salivary flow represents the amount of saliva secreted in response to breathing through the mouth for five minutes. The plasma volume was determined by the Keith-Rowntree method, observing the necessary precaution of reading the unknown against a standard of nearly the same strength. The body weight at the start was 85.6 kg. It dropped to 83.0 kg. after two days without food or water, but with the ingestion of 2500 c.c. (ml.) of fluid (water and ginger ale) it was again restored to normal. (Constructed from the data of Gregersen and Bullock: Am. J. Physiol. 105: 39, 1933.)

of the cervical sympathetic fibers, on the other hand, fails to provoke any secretion." We cannot, therefore, explain the reduction in salivary flow during dehydration on the basis of changes in the reflex arc or in the strength of the stimulus applied to the glands.

The influences which affect the salivary flow must operate through the blood stream. Since dehydration is normally associated with a concentration

*During degeneration of the nerves there is a small continuous flow of saliva known as the "paralytic secretion."

of the blood, it is well to consider the effect which this may have on the activity of the salivary glands. A characteristic of all true secretory cells is that their activity is independent of the composition and the pressure of the blood flowing through them. Likewise, the quality of the secretion which they produce is not, as a rule, conspicuously altered by changes in the composition of the blood. This can be demonstrated for the submaxillary gland by continuous injections of various substances directly into the external carotid artery, from which the gland receives its blood supply (unpublished observations by the writer). A further point is that the activity of the submaxillary gland results in the withdrawal of a very large proportion of the fluid from the blood passing through it. During active secretion induced by stimulating the chorda tympani, for example, the blood flow through the submaxillary gland of a cat or dog is about 5 to 6 ml. per minute per gram of gland,[6] while the secretion rate may be 1 to 2 ml. per minute per gram of gland. Since only one-half of the blood is plasma, the secretory cells must have extracted between one-third and one-half of the

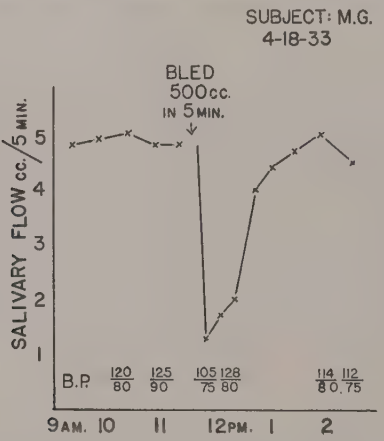

Fig. 370.—Curve showing the reduction in salivary flow caused by the sudden withdrawal of about 10 per cent of the blood from a normal subject. The salivary flow was measured by the response to breathing through the mouth.

total quantity of water in the blood which passes through the gland. A small amount of fluid is also drained off as lymph. These cells are thus capable of withdrawing fluid from the blood when the latter is far more concentrated than it is in dehydration. Consequently, it is highly improbable that the relatively small hemoconcentration brought about by a moderate loss of body water is a direct factor in causing a diminished secretion of saliva. The possibility becomes even more remote when we recollect that hemorrhage, which if anything dilutes the blood, also lowers the salivary flow (see Fig. 370).

Since the glands secrete large volumes of fluid in proportion to their own weight, their activity must depend intimately upon the blood supply. If the carotid artery is partially occluded while the submaxillary gland is being stimulated through the chorda tympani, there is a prompt fall in the secretion rate. Gesell[11] has shown that the increase in blood flow through this gland during activity is directly proportional to the volume of saliva produced. He has also

demonstrated[40] that the blood flow through the resting gland may be reduced to one-seventh of its original value by a hemorrhage amounting to only 10 per cent of the total blood volume, in spite of the fact that the blood pressure may be unaffected by the hemorrhage. The compensatory vasoconstriction which accompanies a decrease in blood volume apparently restricts the blood supply to the salivary glands as well as to other areas in the body supplied with vasoconstrictor nerves. This gives us a sensible explanation for the reduced salivary flow in dehydration, provided it can be shown that salivary secretion and blood volume undergo parallel changes in dehydration and in other general conditions which are conducive to thirst.

Concurrent changes in salivary flow and plasma volume may be seen after water deprivation, after ingestion of a large meal taken without water, after profuse sweating in a hot bath and when the body water has been depleted by the diuresis incident to the intravenous injection of concentrated (50 per cent) sucrose solution (16-18 grams per kg. body weight). Fig. 369 shows the observations made on a human subject during two days without water. The correlation in this and other experiments between salivary flow and plasma volume is strongly indicative of the dependence of thirst upon a reduction in the fluid volume of the blood. This is particularly well illustrated in an experiment with hemorrhage (Fig. 370). The subject was bled 500 ml. in five minutes from the right antecubital vein. There was only a small and temporary fall in the blood pressure, indicating the presence of an effective compensatory vasoconstrictor mechanism, but the salivary flow immediately fell to one-fifth of its previous level and did not return to normal for over an hour, presumably the time required for restoration of the fluid volume of the blood. Similar results have been obtained on dogs. Putting all the above facts together, we arrive at the conclusion that the decrease in plasma volume caused by depletion of the water content of the body is significant as the first step in the physiological mechanism of thirst which signals the need for an increase in the water intake. A dry mouth is therefore an important physical sign of a lowered blood volume, a fact which the surgeon has inferred from his practical experience; namely, that a patient with a dry mouth is a poor surgical risk and cannot withstand hemorrhage as well as the patient whose tongue is moist and glistening.

Although this interpretation offers a reasonable account of how the intake is adjusted to meet the water deficit in simple dehydration (loss of water alone), one cannot leave the question without considering a number of unexplained observations which indicate that there may be other physiological changes besides those described above, perhaps involving mechanisms as yet unknown, which also determine the presence or absence of the local sensation of thirst or the subjective impression thereof. For one, the accuracy with which the dog, for example, estimates a water deficit is rather surprising. The dehydrated animal will ingest an amount of water closely approximating the deficit in a few minutes, sometimes drinking without interruption and then stopping abruptly, apparently satisfied.[1] How does the animal judge his needs so closely? It is obvious that enough water to relieve the dehydration could not be absorbed in such a short period of time. From his studies on sham drinking in dogs with esophageal fistulas, Bellows[9] concludes that there are at least two processes involved. He states that: "Passage of an excessive amount of water through the mouth and pharynx confers immediate but tem-

porary satisfaction of thirst. The repetitive act of drinking and swallowing water is inhibited when the ingested water deficit enters the gut below the upper esophagus. The short period of temporary satisfaction secured by the passage of water through the mouth and pharynx is superseded by the delayed process of permanent satisfaction operating lower in the gut." The presence of water in the gut does not immediately inhibit drinking. If the estimated deficit is administered through a gastric fistula the animal will, if permitted, nevertheless promptly drink as much as he would have ingested without water in the stomach. If, on the other hand, water is withheld for ten to fifteen minutes the dog has lost his desire to drink.

For many years it has been known that the intravenous injection of hypertonic salt solution gives rise to thirst. On the basis of this fact a number of investigators have favored the view that the water intake is regulated according to the concentration of electrolytes in the body fluids. It is quite true that the serum electrolyte concentration tends to increase in severe dehydration, but it should also be noted that when the dehydrated dog is given water *ad libitum,* the electrolyte concentration in the blood frequently drops considerably below the initial normal level. In other words, according to this criterion he takes more water than is required to restore his body fluids to the normal state. That the answer is not as simple as one might suppose is further demonstrated by a detailed study on dogs of the drinking in response to salt.[68] In any one animal the amount of water ingested under standard conditions is directly and quite accurately proportional to the quantity of sodium chloride injected. Nevertheless one animal may regularly drink twice as much as another after the same dose. And again we must emphasize that the dog completes his drinking in a few minutes; that is, before the ingested water could effectively reduce the electrolyte concentration in the body fluids. Moreover, hypertonic solutions of the non-electrolytes sucrose, sorbitol, and to less extent glucose, are also effective in causing thirst. At any rate it should be noted that changes in salivary flow may constitute an important part of the thirst mechanism in these experiments. In man, the thirst caused by the injection of 300 ml. of 5 per cent sodium chloride (and the same is true when hypertonic sodium chloride is taken by mouth) is associated with an immediate reduction of the salivary flow to one-tenth or less of its normal value. If, however, the subject drinks 500-800 ml. of water about twenty minutes before the salt is given, the sensation of thirst is slight or entirely absent and the salivary flow remains essentially unchanged.

Gilman[42] has suggested that thirst might be determined specifically by dehydration of the intracellular compartment, a view favored also by Dill.[22] This would account for the thirst caused by salt and other substances which cannot penetrate the cell barrier, and, as Gilman noted, the absence of thirst immediately after the intravenous injection of urea to which the cell wall is freely permeable. As additional evidence Gilman cites the well-known fact that the experimental depletion of the extracellular electrolytes by intraperitoneal injection of isotonic glucose (Darrow and Yannet[21]), which results in a drastic decrease in both plasma and interstitial fluid volume as water moves into the intracellular compartment, is not associated with thirst. Dogs so treated will not drink water in spite of the fact that the mouth is exceedingly dry. This behavior may, however, be related to an impairment of the sensory

mechanism underlying the sensation of thirst, for McCance[94] reports that salt deficiency in man results in a loss of taste. Or speculating still further, it may be that an entirely different mechanism concerned with control of salt balance is taking precedence over the control of water balance. Clearly, the ingestion of water under these circumstances would merely serve to aggravate the already serious dilution of the electrolytes in the body fluids. One might add that the same disturbance in water balance (depletion of extracellular electrolytes and shift of water from extra- to intracellular compartment without altering the total body water) brought on gradually by sucrose diuresis and maintained by a salt-free diet, has been found to increase the daily water intake by three- to fourfold. (Unpublished observations by J. H. Holmes.) The evidence on the relation of intracellular hydration to thirst is therefore discouragingly contradictory at present.

Although several endocrine glands have, under special circumstances, been shown to affect the water intake, there is little indication that they play an essential role in or directly influence the thirst mechanism itself. For example, it has been noted that a subcutaneous injection of pitressin, administered twenty to thirty minutes prior to the injection of hypertonic salt, inhibits drinking for about ten minutes.[9] That the adrenal cortex may influence thirst is shown by the recent observation that large doses of desoxycorticosterone in normal dogs produce polydipsia.[106] Excessive doses of thyroid also increase the daily water intake.[75]

Dehydration.—The length of time during which life may be sustained without water differs greatly with the species.[89] Moths and serpents, for example, can live for very long periods with no water, and among the mammals the camel shows an extraordinary resistance to dehydration. Most animals, however, can exist without water for only a limited period, the length of which is modified by environmental conditions and bodily activity, and probably also by the differing capacity of individuals of the same species to withstand dehydration. Man has been known to survive eighteen days under average conditions of temperature and humidity, but under extremes of heat and exposure to the sun death may occur in two or three days. McGee[95] reports the remarkable case of a Mexican lost in the desert who walked and crawled 150 miles during a period of seven days and managed to sustain life by drinking his own secretions. Under ordinary laboratory conditions, dogs succumb to water deprivation in from two to eight weeks, and rabbits in about fourteen days.

Dehydration is frequently an important clinical problem. In the diarrheas of infancy and in Asiatic cholera, large quantities of water may be lost in the stools. Vomiting, and in particular the vomiting associated with pyloric obstruction, depletes the supply of body water so rapidly that 20 per cent of the body weight may be lost in one or two days.

Some of the tissues are more dependent than others upon their water supply in order to function. It is said that muscles, for example, may lose from 10 to 20 per cent of their total water without impairment of function, as determined by electrical records of activity of muscles after removal from the body. The skin can lose an even larger proportion of its water without permanent damage to itself or to the organism. Marriott has emphasized that this is not true for the blood, and that death from dehydration is caused by an increased viscosity of the blood. The circulation through the tissues is impaired and the blood tends to stagnate in the capillaries; in extreme dehydration the blood becomes so viscous that there may be no bleeding from deep cuts.

Water Intoxication.—Harmful effects from the ingestion of large quantities of water are not usually observed if the kidney is normal. In patients with impaired renal function, however, the administration of large doses of water may produce headache, dizziness, vomiting and cramps, together with a marked increase in weight and an increase in the blood pressure. This condition, which is known as "*water intoxication,*"[112] can be readily produced in dogs by giving water by stomach tube, in combination with injections of posterior pituitary extract. Since the latter inhibits the excretion of water but does not interfere with its absorption from the gastrointestinal tract, the animals become overloaded with water. Water intoxication in dogs is characterized by asthenia, restlessness, diarrhea, nausea, retching, vomiting, tremor; salivation, muscle twitching, ataxia, convulsions (from increased intracranial pressure) and stupor or coma. If the forcing of water is continued, death ensues. The symptoms can be rapidly relieved by injecting hypertonic salt solution or by giving urea, both of which overcome the effect of the pituitary extract and produce diuresis and withdrawal of water from the tissues.

The disturbances in bodily function associated with water intoxication are presumably caused by a dilution of the body fluids with respect to salts. A similar situation is encountered in heat cramps. Men who work in boiler rooms, steel foundries and other places where they are continually exposed to high temperature, lose large quantities of salt in the sweat. If under these conditions the water content of the body is restored only with water, the concentration of salt in the body fluids decreases to a point where the normal functions are disturbed. Although in this case the water content of the body is not increased above normal, the symptoms which appear are similar to those produced by water intoxication. Heat cramps can be avoided by drinking a solution of sodium chloride instead of water. It is said that this solution, which ordinarily is quite distasteful, is taken with great satisfaction under conditions conducive to excessive sweating.

The dependence of the total water content of the body upon the retention of salts has already been noted and may be illustrated in a number of other ways. For example, the dehydration which accompanies experimental pyloric obstruction in dogs cannot be alleviated by water alone. With the continued secretion of gastric juice, the animal loses considerable quantities of chloride and some sodium. The preponderance of base left in the blood is excreted by the kidneys with the result that both the sodium and chloride in the extracellular fluids are rapidly depleted. Under these circumstances water has no therapeutic value and is merely excreted. The same end result may be produced in a dog by allowing the pancreatic juice to be drained from the body through a fistula.[38] Since this secretion consists mainly of sodium bicarbonate, the body is left with a relative excess of chloride which is eliminated by the kidney. In this case also the progressive dehydration is not prevented by allowing the dog water *ad libitum;* nor is it alleviated by feeding meat, in which the fixed base is almost entirely potassium. This base, which cannot take the place of sodium in the extracellular fluids, is merely excreted. Another illustration is the gradual loss of body fluid which occurs in individuals living on salt-free diets.[94] Also it is a matter of common clinical observation that in patients whose renal mechanism for the excretion of salts is impaired, the addition of salt to the diet causes retention of fluid; and further, that the

problem of removal of edema fluid is in reality a problem of bringing about the excretion of sodium chloride. The storage of water goes hand in hand with the storage of salt; the one cannot be retained for any considerable length of time without the other. Hence, either one given alone usually acts as a diuretic.

The Influence of the Central Nervous System and Hormones Upon Water Exchange.—Among the oldest observations which indicate a dependence of the total water exchange upon the central nervous system, is the finding of Claude Bernard that a puncture in the floor of the fourth ventricle causes an increase in the urine flow. Further evidence that the central nervous system may affect the total water exchange is the common association of diuresis with nervous excitement.

Brain tumors in the region of the pituitary gland are sometimes associated with an extraordinary polyuria and an insatiable thirst, a disease known as diabetes insipidus. Cases have been reported in which 35 to 40 liters of urine were secreted daily. Since the administration of a small amount of pituitrin (posterior lobe extract) ordinarily restrains the abnormal elimination,*[138] the belief has grown up that the disturbance is the result of hypofunction of the posterior lobe of the pituitary. Ranson and his co-workers[35] have shown that the functional integrity of the posterior lobe is dependent upon its nervous connections with the nucleus supraopticus. In cats, bilateral destruction of this nucleus results in polyuria and atrophy of the posterior lobe. There has been considerable disagreement among observers as to the original cause of the increased water output, that is, whether it is due initially to an abnormal thirst or to an increase in the elimination of water by the kidneys. That the thirst mechanism in this disease is functioning abnormally seems to be indicated by reports that the desire for water cannot be abolished by desensitizing the buccal mucosa with local anesthetics. This contention that the thirst mechanism is abnormal is not supported by some recent observations which showed that the thirst in a severe case (urine output 18-20 liters per day) could be completely relieved by merely increasing the water intake sufficiently to maintain the normal plasma volume and body weight.[51] Under these conditions the salivary flow also rose to a normal level. Furthermore, when relief from thirst was obtained by giving pituitrin, the plasma volume increased. Indeed this patient showed the same parallel changes in plasma volume and salivary flow as a normal subject.

Other glands of internal secretion have important though as yet little understood effects on the total and internal fluid exchange. The adrenal cortex, for example, seems to be concerned in regulating the excretion of electrolytes and in maintaining the normal distribution of fluid between the extra- and intracellular compartments.[60, 83] Some investigators ascribe specific diuretic effects to the anterior pituitary gland and the thyroid, but these effects may be simply the result of changes in the metabolic rate. The periodic retention of fluid during the oestrus cycle in lower animals and the premenstrual edema in women are further indicative of the existence of complex relations between the water balance and the internal secretions.

*The effect of pituitrin on the kidney will be considered in the following section (Part IX).

CHAPTER LXXX

INTERNAL FLUID BALANCE

Translocations of water in the organism can only to a certain extent be explained by known physical and chemical forces. In many instances the living membrane participates actively in the fluid exchange, causing water and solutes to move in a direction opposite to the concentration gradients. Where this so-called vital process does not participate, the movement of fluid is largely determined by osmotic and hydrostatic pressures. Chemical hydration and electrical potentials are also known to affect the exchange of water within the organism, but it is difficult at present to evaluate their significance quantitatively.

As we have seen above, the membranes which separate the vascular from the interstitial compartments and those which separate the latter from the intracellular compartment have peculiarities of permeability which maintain an unequal distribution of solutes in the three compartments. The barrier between plasma and tissue fluid permits the passage of all constituents in the plasma, with the exception of the proteins. The barrier between the extra- and intracellular fluids is not only impermeable to proteins but also normally prevents the passage of sodium, potassium, chloride and a number of other constituents. Without these barriers, which are permeable to water but which discriminate against the dissolved substances, the force known as osmotic pressure would no longer exist.

Osmotic Pressure.—This is the result of an unequal distribution of water on two sides of a membrane. If an aqueous solution of sucrose is separated from pure water by a membrane which permits the free passage of the water but not of the sugar, water will move into the solution until the sugar theoretically attains infinite dilution. By raising the hydrostatic pressure of the solution, a point is finally reached at which the water molecules move out of the solution at the same rate as they enter. The pressure which is required to prevent addition of water to the solution is a measure of its osmotic pressure. It so happens that the osmotic pressure which is developed by the sugar in a system such as the above is equal to the pressure which the same number of molecules of a gas would exert if they were confined to the same volume as the sugar solution. From this one might be led to suppose that the sugar, or solute, in some mysterious way attracts water in an effort to enlarge the space in which it is confined. *Water moves across the membrane not because of some peculiar attraction of the sugar molecules for water but because the sugar displaces some of the water molecules and therefore the concentration of water is less inside than outside.* Hence, water moves into the solution until the diffusion pressure of water is the same on both sides of the membrane. Since the diffusion pressure is dependent not only on concentration but also on the hydrostatic pressure, the movement of water into the solution ceases when the hydrostatic pressure there has risen to a point which counterbalances the effect of unequal concentration of water on the two sides of the membrane. If we now substitute for sugar some substance, let us say sodium chloride, to which the membrane is permeable but which, nevertheless, diffuses through it more slowly than the water, the difference in concentration of water on the two sides of the membrane will be maintained only temporarily, and the osmosis will therefore be cor-

respondingly temporary. In the body we have situations analogous to both of the cases just described. Long ago Starling[133] pointed out that the plasma proteins exert a continuous osmotic pressure because the capillary wall is practically impermeable to them. The crystalloids which pass through it with ease exert no osmotic pressure unless their distribution is altered suddenly, and then their effect on movement of water is only transient. Therefore, the effective osmotic pressure of the plasma is usually dependent solely upon the plasma proteins. In general their osmotic pressure is balanced by the hydrostatic pressure in the capillaries. However, the tissue fluid immediately adjacent to the blood capillaries contains a small amount of protein, enough to reduce the effective osmotic pressure of the plasma. The tissue fluid is also under a certain amount of hydrostatic pressure (the latter being influenced by the degree to which the tissue spaces and cells are distended with fluid) which reduces the filtration pressure in the capillaries.

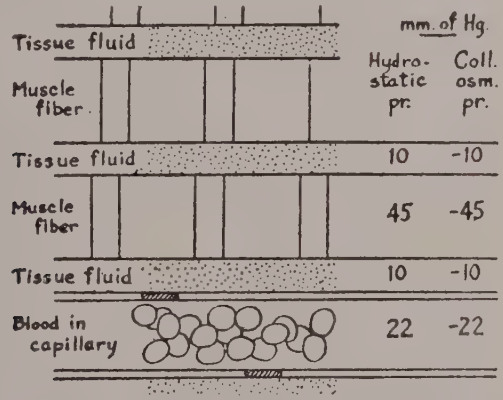

Fig. 371.—Diagram representing the balance of forces concerned in the osmotically steady state in average mammalian muscle tissues. It should be emphasized that the values for hydrostatic and turgor pressures are hypothetical because it is not known whether the colloid osmotic pressure of muscle measures the force effective in controlling the movement of water. (From Adolph.[2])

The osmotic and hydrostatic pressure relationships between blood and tissue and between tissue fluid and cells are shown in the accompanying diagram (Fig. 371). It shows that the equilibrium is determined mainly by four factors: "... the blood's hydrostatic pressure within the exchanging vessels, the turgor pressure and deformational tension of the tissue around the capillaries, the effective osmotic pressure of the blood plasma, and the effective osmotic pressure of the tissue cells."[72] With the exception of intracellular hydrostatic pressure, these forces have all been measured. Since the limiting membranes are not rigid, it is apparent that the hydrostatic pressure and the effective osmotic pressure must balance in each compartment.* Great flexibility in the movement

*The notion that a considerable portion of the water in the body is *"bound"* has not been supported by recent experimental evidence. Hill, using measurements of vapor pressure as the test for free water, estimates that the amount of bound water in the blood is less than 2 per cent of the total. In mammalian muscle it has been found that at least 94 per cent of the total water is capable of diluting electrolytes. Ultrafiltration experiments on blood serum, gelatine, glycogen, casein and starch show little evidence of bound water in these substances. Practically all the water in the body is free in the sense that it is available for dissolving substances and for taking part in fluid exchange.[77]

of fluid in such a system may be achieved by the body through changes in capillary pressure and permeability. When and to what extent changes occur in the intrinsic permeability of the capillary wall is difficult to determine.[77] In general it seems to be enhanced by capillary dilatation, but since the latter is also as a rule accompanied by increased capillary pressure, the relative importance of the two factors in furthering filtration cannot be estimated readily. Since vascular adjustments may be attended by alterations in capillary pressure and caliber, it is clear that the vasomotor system is a prime factor in preventing or promoting the local and general movement of fluid between blood and tissues. Through its integrative action the vasomotor center may permit fluid to be filtered in one part of the circulation and absorbed in another without significant disturbances in the total volume of the plasma. Likewise it compensates for exchange of fluid between the plasma and the external environment.

Evidence of the movement of water between blood and tissues can sometimes be obtained from changes in concentration of hemoglobin or plasma protein. The deduction from such measurements, however, is based on the assumption, frequently erroneous, that the total amount of plasma protein or the number of red cells in circulation remains constant (see Table CXVI). This method has the further disadvantage that it yields no information about the absolute amount of fluid exchanged, a matter of the greatest importance. A dependable method for estimating the absolute changes in plasma volume is essential for a complete investigation of the physiological conditions which determine the balance of fluid between blood and tissues. At present the most satisfactory way of measuring rapid changes in the plasma volume is to follow the changes in concentration of a slowly diffusible dye injected intravenously in a measured amount, the method described in Chapter LXXVIII.

Gravity.—The effect of capillary pressure on the exchange of fluid between blood and tissues is illustrated by quiet standing. That the increased venous pressure in the lower extremities under these circumstances results in a loss of fluid from the circulation is shown by the rise in plasma protein concentration and by the increase in the volume of the legs. If the subject then reclines, the fluid is soon restored to the circulation. Moving about will, to some extent, produce the same result by relieving the venous congestion and facilitating the drainage of lymph from the legs. Landis and Gibbon[78] have demonstrated that in experimental venous congestion filtration is at first rapid, but that at the end of about thirty minutes there is no further change because the tissue fluid pressure has risen to a point where it counterbalances the capillary pressure. A critical discussion of the various factors involved may be found in the review by Landis.[77]

Muscular Exercise.—Marked changes in the distribution of water and electrolytes have been found to occur during muscular activity. It has been known for some time that activity of skeletal muscle causes an increase in its weight.[7] More recently Fenn and co-workers[29, 30] have shown that the muscle cells lose potassium and take up sodium, and there is an increase in the volume of extracellular fluid in the active tissue. In man, vigorous muscular exercise produces a rise in the concentration of the blood.[23] If a measured amount of a slowly disappearing dye (T-1824) is injected intravenously and its concentration in the plasma determined at frequent intervals (see Fig. 367), it is possible to obtain a fairly accurate estimate of the quantity of fluid which leaves the circulation during exercise and the rate at which this fluid is subsequently restored. In the experiment shown in Fig. 372, the subject lost 470 ml. of fluid from the

plasma in ninety seconds (a decrease of 16 per cent in the plasma volume), whereas complete restoration of this fluid to the circulation required about an hour. The plasma protein concentration and the per cent of red cells also reflect these changes.

Adrenalin and the Sympathetic Nervous System.—From the statements made earlier, one might expect that stimulation of the sympathetic system and the secretion of adrenalin would greatly alter the internal fluid balance, since they have a marked effect on the pressure and distribution of the blood. Indeed it has been reported that continuous intravenous injections of adrenalin and intense sympathetic discharge will cause hemoconcentration and reduce the volume of plasma to a degree which produces shock.[36] Observations made by the writer and two associates on unanesthetized dogs[53] and cats[58] in which the plasma volume changes were followed during continuous intravenous injections of adrenalin have not confirmed these reports. In unanesthetized dogs, the effect of adrenalin in this respect is apparently unpredictable. The plasma

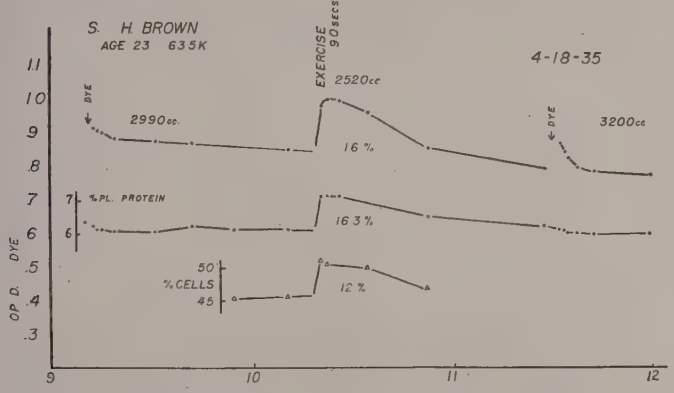

Fig. 372.—Showing that a short bout of vigorous exercise (running at top speed for ninety seconds on a treadmill) results in a marked decrease in plasma volume as measured by the plasma concentration of the dye (T-1824) injected at the start of the experiment. The change is also reflected by the rise in the plasma protein and erythrocyte content of the circulating blood. Full restoration of the plasma volume requires from thirty to sixty minutes. This experiment illustrates the rapidity with which fluid shifts between blood and tissues may occur. (Unpublished experiment by Gregersen, Dill and Meade.)

volume may rise, fall or remain unaltered; but in any case, the change with physiological doses is not great enough to impair the circulation. In cats, there is no significant change. Removal of the sympathetic system in this species produces as a rule a striking increase in the plasma volume, a result one would expect inasmuch as the blood pressure is still approximately normal in spite of the loss of vasomotor tone. In the dog the results have so far been conflicting.

The ultimate explanation of these and many other observations of a similar nature requires more information concerning the fundamental problem of control of capillary pressure, especially its relation to the vasomotor system. It is useful to recall that the capillary pressure is very sensitive to changes in venous pressure. Unfortunately, our knowledge of the vasomotor control of the veins is less complete than on the arterial side in which pressure changes

appear to take place without much effect on the capillary pressure. A clear illustration of the latter is the fact that in the unanesthetized dog the arterial pressure may be reflexly raised to the neighborhood of 200 mm. Hg for an hour by occluding both carotid arteries, without thereby producing any change in the plasma volume.[46]

Other Hormones.—Among the hormones which influence the distribution of fluid between blood and tissues is the vasopressor principle (pitressin) from the posterior lobe of the pituitary. When this substance is injected alone, there is no marked change in the concentration or the volume of the plasma; but if water is ingested at the same time, diuresis is delayed for from three to four hours and the water content of the blood is increased. Since hydremia does not result from the ingestion of a similar quantity of water alone, it would appear that pituitrin interferes with the removal of the absorbed water from the plasma. This explanation is supported by the observations that pituitrin retards the escape from the blood stream of a large variety of substances, either foreign or naturally occurring in the plasma. Whether the effect is caused by an intrinsic change in permeability of the capillary wall or is simply the result of changes in the capillary circulation is not known.

CHAPTER LXXXI

THE CEREBROSPINAL FLUID

The formation and absorption of cerebrospinal fluid constitute a problem of internal fluid exchange which is frequently a matter of practical concern. Treatment of hydrocephalus and of eclampsia in its acute states, not to mention the multitude of cranial injuries that result from automobile accidents, requires a clear understanding of the factors which determine the movement of water between blood and the cerebrospinal fluid.

Under normal conditions, the cerebrospinal fluid is a clear, limpid liquid, devoid of protein and containing very few cells (4-6 per cubic mm.). It fills the ventricles of the brain and the subarachnoid space of the cerebrospinal axis, from which it may be collected by a lumbar or cisternal puncture. Its total volume in man has been variously estimated at between 60 and 150 ml. However, if a needle is left in the cisterna magna, very much larger quantities than this can soon be collected, showing that the fluid is continually being renewed. It circulates from the lateral ventricles where it is secreted by the choroid plexuses, passes through the third ventricle, the aqueduct of Sylvius, to the fourth ventricle, from which it escapes into the subarachnoid space by way of the foramina of Magendie and Luschka, and is eventually absorbed through the arachnoidal villi into the venous sinuses.[145] A small amount of fluid is also added to the subarachnoid space from the perivascular spaces of the brain.

That the cerebrospinal fluid is secreted by the choroid plexus was demonstrated in a striking manner by Dandy. He showed that the internal hydrocephalus which develops after obstructing one foramen of Munro is prevented by extirpating the choroid plexus on the same side. Absorption of the cerebrospinal fluid into the venous sinuses was demonstrated by Weed, who, by injecting Prussian blue reagents into the subarachnoid space and subsequently fixing the brain in an acid medium to precipitate them, found that the granules had passed into the venous sinus through the arachnoid villi. Except for a small absorption through the lymphatic vessels by way of the perineural spaces, the foreign solution did not pass through membranes in any other portion of the subarachnoid space.

So strong is the similarity between the composition of cerebrospinal fluid and an ultrafiltrate of serum that a number of observers have been led to ascribe the production of cerebrospinal fluid to a purely physical process. That osmotic equilibrium exists between spinal fluid and serum is shown by the identity of the freezing points of these two fluids. Moreover, the difference in chloride concentration of spinal fluid and serum is in accord with the Gibbs-Donnan equilibrium. But beyond this point, according to Peters,[104] the evidence fails to substantiate the theory that spinal fluid is a true ultrafiltrate of serum. Glucose, nonprotein nitrogen and urea do not appear in the concentrations to be expected if true equilibrium existed between the two fluids. The distributions of bicarbonate, calcium phosphate and total base likewise show a discrepancy which is

Fig. 373.—Comparison of the effects on cerebrospinal fluid pressure of intravenous injections of hypertonic solutions of sodium chloride, glucose, and sucrose, showing that sodium chloride and to a lesser extent glucose cause a secondary increase in pressure which does not occur with sucrose. (From Bullock, Gregersen and Kinney.[15])

not explainable. Added to this is the observation that a number of dyes which diffuse easily from blood to lymph do not enter the spinal fluid at all. These facts suggest that the blood-spinal fluid barrier takes an active part in the distribution of substances between blood and serum.

In the recumbent position, the cerebrospinal fluid pressure in man averages 130 to 150 mm. of water, regardless of whether the pressure is measured in the cisterna magna or in the lumbar region. In the sitting position, the lumbar pressure rises to 200-250 mm. of water. No demonstrable changes are produced by altering the arterial pressure, but an increase in the venous pressure has an immediate effect. This may be demonstrated very simply by pressing on the jugular vein.

Because the cranial contents are enclosed in a rigid case, an increase in the intracranial pressure tends to set up a vicious circle. As the pressure rises, interference with the venous outflow retards absorption of spinal fluid and at the same time increases filtration because of a rise in the capillary pressure in the choroid plexuses. This situation may be produced by a cranial tumor or by swelling of the brain tissues as a result of trauma. Unless the vicious circle is broken at some point, the patient becomes comatose and finally succumbs. Relief of pressure is obtained with varying success by opening the skull, by removing fluid with lumbar or cisternal puncture and by increasing the tonicity of the blood.

The effect of alterations in the tonicity of the blood upon cerebrospinal fluid pressure was first demonstrated by Weed and McKibben.[146] They found that intravenous injections of water caused swelling of the brain and increased intracranial pressure, whereas the reverse was true with injections of hypertonic sodium chloride solution. Clinical experience with concentrated salt solution soon revealed that relief was only temporary and was followed by a subsequent rise in pressure far in excess of the original. From the discussion in the preceding pages, it is evident that the reason for this secondary rise lies in the fact that sodium chloride diffuses into the tissues, which therefore retain more water than was present before the injection. Concentrated glucose solutions have a similar although less extreme effect. With injections of concentrated sucrose, the secondary increase in pressure is entirely absent,[15] and this has been shown to be true also for sorbitol.[114] The molecular weight of sorbitol is one-half that of sucrose and therefore a given dose of 50 per cent solution of sorbitol is more effective in reducing the spinal fluid pressure than the same amount of sucrose.[114]

The differences in the effects of salt, glucose, and sucrose upon spinal fluid pressure in dogs may be seen in Fig. 373. Glucose and sodium chloride are partly stored in the tissues, but sucrose is rapidly excreted in toto, taking with it considerable quantities of body water. Of these three, therefore, sucrose is the most effective as a means of keeping down the cerebrospinal fluid pressure.

It should be emphasized that when concentrated solutions are given intravenously, the plasma volume is temporarily increased by a much greater amount than the volume of solution injected. For example, intravenous injection of 250 ml. of 50 per cent sucrose in twenty minutes into a dog weighing 20 kg. practically doubles the plasma volume. Sudden increases of this magnitude are very apt to embarrass the circulation, and therefore these solutions should in practice be given very slowly.

Evidence of impairment of renal function as well as of pathological changes in the kidney (swelling of the tubule cells with subsequent degenerative changes in the protoplasm and nucleus) has been observed in animals receiving large injections of hypertonic sucrose.[64, 66, 82] The changes are evidently reversible, for the histological picture returns to normal within seven to fourteen days after the last injection. The exact cause of the damage is not known. It may be either a direct effect of the sucrose on the kidney cells or an indirect effect resulting from sudden and large disturbances in the internal distribution of water and electrolytes and the rapid loss of both salt and water during the severe diuresis. There is some indication that the degree of damage depends upon the rate and amount of the injection of sucrose and upon the previous fluid and electrolyte balance of the animal. In dogs, the danger of impairing renal function is minimized by injecting the sucrose slowly (under 2 ml. per minute) and by maintaining the animals on a high salt diet.[67]

PART IX

THE KIDNEY

By Magnus I. Gregersen

CHAPTER LXXXII

THE KIDNEY

The kidney is so obviously concerned in the elimination of nitrogenous waste products that one might be inclined to regard it merely as an excretory organ. This view, however, does not do justice to its complex activities. For example, we have seen in the preceding chapter that the kidney is also involved in the maintenance of the water balance. Even this role appears to be merely a consequence of the kidney's chief function, namely, that of regulating the composition of the blood. Whereas urine formation may be accelerated by the ingestion of water or salt alone, there is usually little or no diuresis following the ingestion of isotonic sodium chloride. The kidney is influenced more readily by disturbances in the composition of the body fluids than by changes in the total water content of the body.

The kidney should be looked upon rather as a filter plant which not only removes the end products of protein metabolism (urea, sulfate, phosphate, etc.) and other waste products or foreign substances that may be dissolved in the plasma, but which also makes continual adjustments in the relative and absolute concentrations of the normal constituents of the plasma. In order to serve the body effectively in these capacities the filter plant must have a large turnover. It is estimated that the blood flow through the kidneys in man is about one liter per minute. This means that a volume equal to all the blood in the body flows through these organs every five minutes. Furthermore, it should be noted that the blood in its passage through the kidney must traverse two capillary beds in series. At least one-quarter of the fluid contained in the blood is filtered off in the first set of capillaries; nearly all of it is then returned to the blood stream in the second set after being subjected to what might be termed a "purification process" by the kidney cells. The volume of fluid subjected to this treatment every hour is greater by nearly three times than all the plasma in the circulation. By thus standing guard over the plasma composition, the kidney is to a very great extent responsible for the constancy of the "internal environment" of the body. It is not surprising therefore to find that disturbances in renal function may quickly manifest themselves in general bodily changes, such as edema, dehydration or toxemia. Since these conditions may also arise from other causes, it is often important clinically to determine whether or not renal function has suffered a change, and if so, to assess the nature and extent of renal damage. This requires an understanding, first, of the processes occurring in the normal kidney and the experimental methods by which they have been revealed, and second, a knowledge of the physiological

factors that control these processes. Only in this way is it possible to distinguish between cause and effect and to exercise sound judgment in the treatment of renal disease and allied conditions.

A. THE STRUCTURE OF THE KIDNEY

The truism that function is related to structure is nowhere more clearly illustrated than in the kidney. So much can be learned about the function of this organ from a study of its structure that a brief review of the anatomy of the renal elements concerned in urine formation is in order.

1. The Functional Unit

The Structure of the Nephron in Man.—The adult human kidney contains about 1,000,000 functional units known as nephrons. Each nephron consists of an unbranched tortuous tubule which at its origin in the cortex of the kidney is dilated to form a capsule (Bowman's capsule) enclosing a cluster of capillaries (the glomerulus). The latter structure is known as the renal or Malpighian corpuscle. In the vicinity of the Malpighian corpuscle the tubule undergoes a series of convolutions, then proceeds as a straight tubule for a variable distance into the medulla of the kidney; here it makes a sharp bend returning again to the vicinity of the same corpuscle to undergo another series of convolutions before emptying into a collecting tubule. Many of the latter join together to form a collecting duct, which proceeds in a straight course through the medulla to the pelvis of the kidney. In the order mentioned, the various parts of the tubule are known as (1) the proximal convoluted tubule or proximal segment, (2) the straight segment or loop of Henle, (3) the distal convoluted tubule or distal segment, and (4) the collecting tubule. Although this division is based merely on external configuration and differences in cell structure, it is justified also by differences in function.

The location of both the proximal and distal convoluted tubules in close proximity to the renal corpuscle of the same nephron is the result of embryological development.[18] A tubular anlage first appears as an S-shaped renal vesicle near the end of each branch of the developing collecting ducts. One end of this S-shaped structure connects with the collecting duct, while the other forms an invaginated bowl which is early invaded by a cluster of blood vessels, the future glomerulus. The tubule is thus anchored at one end by the glomerulus and at the other by the adjacent collecting duct. Between the developing convolutions of the proximal and distal ends, which lie in a nest around the renal corpuscle, a straight segment grows into the medulla to become the loop of Henle.

The Renal Corpuscle (see Fig. 375).—The general structure of the renal corpuscle and its true relation to the uriniferous tubule were demonstrated by William Bowman in 1842.[13] In the adult kidney the renal corpuscle measures about 0.2 mm. in diameter. The capillary tuft or glomerulus is enclosed by a double-walled sac (Bowman's capsule) created as described above by the invagination of the dilated blind end of the tubule. The space between the two layers of this capsule is continuous with the lumen of the tubule. The inner or visceral layer of the capsule is not merely a pouch, but adheres closely to the glomerular capillaries which are "completely covered by epithelium, just as a finger is covered by a glove."[139] It consists of very thin epithelial cells, hardly distinguishable except by their nuclei, and rests upon a structureless basement membrane which is directly in contact with the endothelium of the capillary loops. The blood in the capillaries is thus separated from the capsular cavity by (a) the endothelial wall of the capillaries, (b) the basement membrane, and (c) the visceral epithelium. Normally they form an extremely thin membrane with a total thickness of only 0.001 mm.; but in glomerular nephritis and other forms of renal disease, the various layers undergo thickening and the capsular cavity may become filled with proliferating epithelial

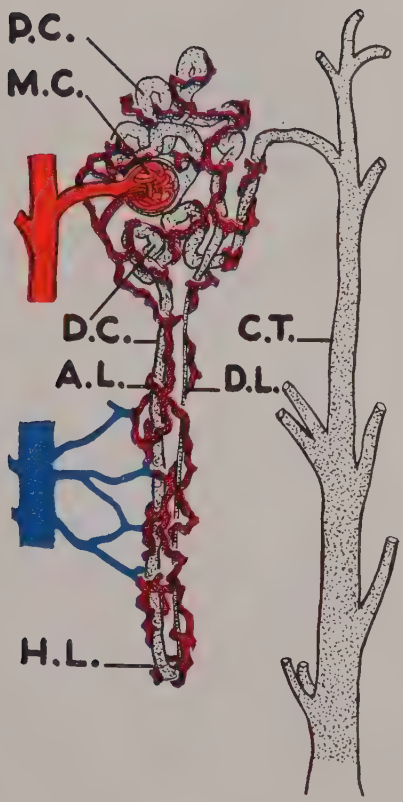

Fig. 374.—Diagram of the nephron with its blood vessels. *M.C.*, Malpighian corpuscle; *P.C.*, proximal convoluted tubule; *D.L.*, descending limb, showing the thin segment; *H.L.*, loop of Henle; *A.L.*, ascending limb; *D.C.*, distal convoluted tubule; *C.T.*, collecting tubule. (Redrawn from Cushny by A. R. Munro.)

cells. The outer wall or parietal layer of the capsule is made up of flattened epithelial cells which change to cuboidal at the junction with the neck of the proximal convoluted tubule. The glomerulus contains about 50 capillary loops, each 0.5 mm. in length. Vimtrup[139] finds no evidence for anastomoses or short circuits between the capillary loops.

The Renal Tubule.—The proximal convoluted tubule is lined with a single layer of cuboidal or columnar epithelium. The cells are distinguishable from those in other parts of the tubules principally by the presence of a "brush border" on the luminal margin. They are coarsely granular, contain large nuclei, and show characteristic cytoplasmic striations extending vertically from the base of the cells. In the resting state the lumen is practically obliterated, but during active secretion it becomes enlarged (see Fig. 376); the cells are then somewhat flattened. Many attempts have been made to relate the changes in microscopic appearance of the cells with activity, but the results have not been helpful in elucidating the secretory mechanism. The studies with dyes are also inconclusive, some showing that granules are formed in the basal portion of the cell and extruded into the lumen, others showing that the granules are formed near the lumen and transported toward the basement membrane. According to the prejudices of the investigators, these observations have been accepted as evidence of secretion from the blood stream into the lumen or of reabsorption from the tubular fluid.

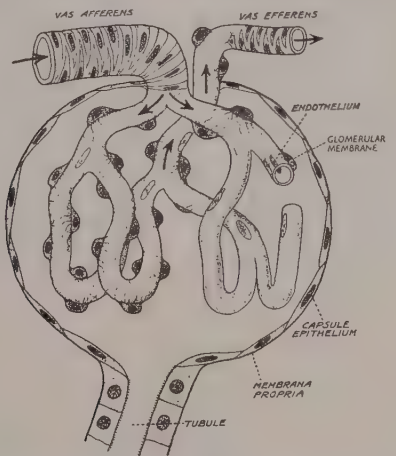

Fig. 375.—Diagram of a *Malpighian Body.* This consists of a tuft of capillaries, the glomerulus, within an invaginated membrane, *Bowman's capsule,* which forms the head of the *tubule.* Note that the capsule epithelium is reflected over the outside of the capillaries of the glomerular tuft. There are in reality many more capillary loops than are shown. Blood enters the glomerulus from the *vas afferens,* and leaves it by the *vas efferens.* The former is definitely larger than the latter. (After v. Möllendorff from Winton and Bayliss.[151])

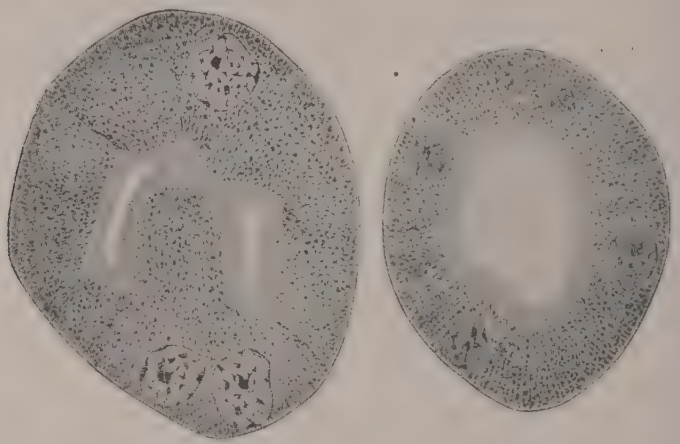
The first portion of the descending limb of the straight segment is microscopically similar to the proximal segment except for the absence of the brush border. At a variable distance along its course this part of the tubule suddenly decreases in diameter from 0.05 or 0.06 mm. to 0.015 or 0.02 mm. The difference in size is due chiefly to the presence of flatter cells (pavement epithelium), the lumen remaining roughly the same. The thin segment continues for some distance along the ascending limb where the cuboidal cells again make their appearance. The thin medullary segment of the nephron is a distinctive feature of the mammalian kidney and is not found in lower animals, with the exception of some birds in which it is poorly developed. It appears to have a special function in connection with the reabsorption of water from the tubular fluid. Its length is variable, depending upon the length of the entire medullary segment itself. The cells of the distal convoluted tubules are similar to those of the thick portion of the ascending limb. They possess no brush border, and the granulations are finer than in the proximal segment. These granulations disappear altogether in the collecting tubules where the cytoplasm is clear and the nuclei very distinct by contrast.

Macula Densa and Polkissen.—Recent anatomical studies on the kidney have revealed special modifications of the smooth muscle cells of the afferent arteriole into cells of an epithelioid nature. There is also a change in the epithelium of the distal tubule where these two structures are juxtaposed. In addition, certain cells form an asymmetrical pad at the arteriolar-capsular junction. This so-called polar pad or *polkissen* is made up of small cells which are interposed between the macula densa and the glomerular membrane. The epithelial cells of the distal tubule lying in contact with this region of the arteriole tend to be columnar rather than low cuboidal, and their nuclei are densely crowded. For the latter reason this area of cells has been termed the *macula densa.* The cells of the *polkissen* and the adjacent *macula densa* are allegedly supplied with nerve fibers and are suspected of having functional significance. For details the reader should consult the reviews by Homer Smith.[128, 130]



A. *B.*

Fig. 376.—Cross-sections of convoluted tubules from kidney of rat. *A*, during slight secretion; *B*, during maximal secretion. (From Sauer.)

Dimensions of the Nephron.—After the kidney has been macerated in hydrochloric acid, it is possible to tease out the intact nephron. When uncoiled, it measures 40 to 60 mm. in length, the variation depending largely upon the extent of the thin segment. Generally speaking, the length of the latter is determined by the location of the renal corpuscle from which the tubule arises and by the proportion of the straight segment present in the medulla. If the renal corpuscle lies in the outer region of the cortex, the straight segment of the nephron usually penetrates the medulla only a short distance, whereas tubules arising from corpuscles situated deeper in the cortex may have straight segments that run the entire depth of the medulla.

Reliable figures for the total number of glomeruli in the kidney have been obtained by Vimtrup.[139] The kidneys were injected through the blood vessels with Prussian blue reagents to stain the glomeruli, macerated in acid and the cortex carefully separated from the medulla.

TABLE CXIX

SPECIES	WEIGHT OF FRESH KIDNEY	NUMBER OF GLOMERULI	
Man, child	?	887,399	estimate
Man, child	?	955,251	total count
Man, adult	?	833,992	estimate
Man, adult	143 grams	867,177	estimate
Man, adult	165 grams	1,233,360	estimate
Dog, 8 kg.	29 grams	407,155	estimate
Dog, 12 kg.	38 grams	507,913	estimate

In a few cases he made total glomerular counts which were found to check closely with the estimates derived from a sample count and the total mass of the cortex. A summary of his results on man and the dog is shown in Table CXIX. From the diameter, length, and number of the capillary loops, Vimtrup calculates that the filtration surface in each glomerulus in the human kidney is equal to 0.78 sq. mm. Since each kidney in man contains about 1 million glomeruli, the total filtration surface in both kidneys is at least 1.5 square meters.

It is useful to compare this with the total surface exposed in the tubules. The size of the tubular lumen varies considerably in different segments and, as we have noted, also shows changes with activity; but if it be assumed that the average diameter is 0.002 mm. and the average length 50 mm., the interior surface of each tubule is 3 sq. mm. The combined tubular surface in both kidneys is therefore in the neighborhood of 6 square meters, or four times as large as the filtration surface in the glomeruli.

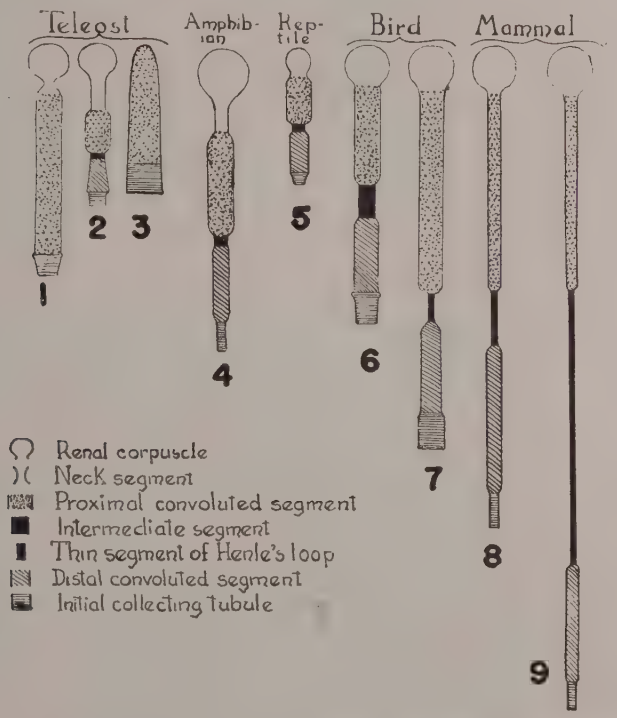


Fig. 377.—Diagram from Marshall showing relative development of uriniferous tubule in various groups of animals. (Redrawn by A. F. Munro.)

The Structure of the Nephron in Lower Animals.—The nephron of the mammal is a fairly complex structure in which the processes occurring in the various morphologically distinct segments cannot be segregated for independent study, at least in the intact unanesthetized animal. In some of the lower animals, however, the situation is simplified to such an extent that it offers opportunities for investigating separately the function of the homologues of certain segments in the mammalian tubule.[90] Some of the possibilities which nature thus presents are shown diagrammatically in Fig. 377. The proximal convoluted tubule (distinguished by epithelial cells with brush borders) is the only segment which occurs in all classes of vertebrates. Particular interest attaches to the sculpin (No. 1) and to the toadfish and goosefish (No. 3); in the two latter the nephron consists only of the proximal segment,

and in the former of proximal segment and glomerulus. In the amphibia, reptiles, and most of the birds, the thin segment or loop of Henle is lacking. This segment, as we have already pointed out, is a distinctive mammalian differentiation, which appears to be associated with the capacity of the kidney to form hypertonic urine. Although it is by no means certain that a given segment functions in exactly the same way wherever it occurs in the vertebrate scale, there is no doubt that the identity of the cell structure at least lends considerable weight to the belief that the potential function of, let us say, the proximal segment is essentially the same in all forms. It should be pointed out, however, that the predominant process occurring in a segment may, to a large extent, be conditioned by the demands of the situation. In the glomerular forms (mammals, etc.) the function of the proximal segment is mainly one of reabsorption. In the aglomerular fish it is purely secretory. There is evidence that a similar reversal of function may occur in mammals after glomerular function has been suppressed by glomerular nephritis. At least one should bear in mind the possibility that tubular functions may, under pathological conditions, show adaptations which alter the process by which urine is formed.

2. Blood Supply

In proportion to its size, the kidney possesses a rich blood supply. The latter is remarkable for its arrangement with relation to the nephron (see Fig. 374). Upon entering the hilus of the kidney, the renal artery breaks up into four or five large branches which run to the boundary zone between the cortex and the medulla where they turn to form the arciform arteries. These give rise to smaller branches (interlobular arteries) which radiate into the cortex of the kidney and along their course give off smaller vessels, the *afferent arteries*, each of which breaks up into a small capillary tuft, the glomerulus, consisting of about 50 capillary

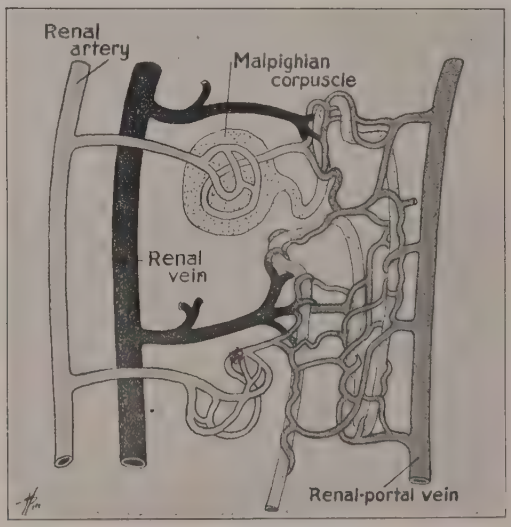

Fig. 378.—Diagram of blood supply of Malpighian corpuscle and of convoluted tubules in amphibian kidney. (Redrawn from Cushny.)

loops and surrounded by Bowman's capsule. The capillaries are twisted and tortuous, but do not anastomose at any point along their course. At the vascular pole of the capsule they again join to form an *efferent artery* which is about one-half the diameter of the afferent (see Fig. 375). It should be noted that changes in the caliber of these vessels can exert profound effects on the glomerular circulation. Upon leaving the renal corpuscle, the efferent artery soon breaks up into another capillary network surrounding the tubules and forming their sole blood supply. In passing through the kidney, the blood must accordingly traverse

two sets of capillaries. In the outer layers of the cortex the efferent artery usually supplies the proximal and distal convoluted tubules of the same nephron. Deeper in the cortex, especially near the margin of the medulla, many of the efferent arteries may not subdivide immediately but take a straight course into the medulla where they form capillary networks of elongated meshes around the straight segments. Hence the blood supply of a tubule is not necessarily derived even in part from the glomerulus of the same nephron. Furthermore, the tubular capillaries from adjacent efferent vessels tend to anastomose. The tubular capillaries empty into a venous system which is more or less confluent with the arterial system.

Homer Smith[130] in a review of the renal circulation points out that a number of anatomists and pathologists have found exceptions to the classical concept which postulates that the blood supply of the tubules is derived entirely from the efferent glomerular arterioles. He concludes that direct arterial connections with the peritubular capillary plexus apparently occur to a small extent even in the normal kidney. These have been described as arising from the interlobular and subcortical arteries and from an occasional small branch of the afferent arteriole. Furthermore the arterio-venous anastomoses found in the kidney, may, as Spanner suggests, represent another channel by which the tubular capillaries can receive blood when the glomerular circulation is arrested.

Renal Blood Supply in Lower Animals.—The description of the renal circulation given above does not hold for reptiles, amphibians and fish. Since many of the deductions as to the function of the nephron in mammals have been drawn from experiments on these lower forms, especially the frog, it is well to note the differences in their renal blood supply.

In the frog, the glomerulus and the tubules are supplied with blood by the renal artery, as is the case in the mammal, but the tubules are also supplied with some of the blood coming from the lower extremities and the trunk through a vessel which has no counterpart in the mammal—the renal-portal vein (see Fig. 378). The blood which supplies the tubules is therefore a mixture from the glomerulus and the renal portal system. By ligating the renal artery, the arterial blood supply to the glomerulus is shut off while the tubules are still supplied by the renal portal vein, thus presumably providing a preparation on which tubular function can be studied separately. All investigators have not agreed, however, that glomerular function is entirely suppressed by this procedure. In aglomerular fish (toadfish and goosefish) the blood supply of the nephron is entirely venous. The development of the arterial supply appears to occur only in the forms that possess glomeruli.

3. Nerve Supply

The kidney is supplied with nerve fibers from the sympathetic by way of the splanchnics and from the parasympathetic by way of the vagi. Before entering the kidney the fibers form a network, the renal plexus, overlying the renal vessels, from which they can be traced along the arteries to all parts of the kidney. Both motor and sensory endings occur in the afferent and efferent arterioles, and fibers have also been found on the glomerular capillaries as well as in and among the cells of the tubules. Nevertheless, it has not been possible to demonstrate that stimulation of the renal nerves has any specific secretory effect. The influence of the nerves on urine formation appears to be produced entirely through their vascular effects. Furthermore, the nerves do not seem to be essential for urine formation since the denervated[73] or re-implanted[105] kidney apparently functions quite normally.

B. THE MECHANISM OF URINE FORMATION

1. Theories of Renal Function

Bowman's Theory.—The modern history of the kidney began with the observations of an English surgeon and physiologist, Sir William Bowman, whose paper *On the Structure and Use of the Malpighian Bodies of the Kidney, with Observations on the Circulation through that Gland,* published in 1842,[13] had a profound effect on the subsequent development of renal physiology. Bowman evolved a theory of urine formation based entirely on his anatomical findings. He reasoned that the glomerulus probably forms a watery fluid since the type of epithelium which embraces the capillary tuft is clearly de-

signed for the easy escape of fluid from the blood stream. Furthermore, the arrangement of blood vessels in the Malpighian corpuscles (large afferent and small efferent artery) appears to effect a retardation of blood flow. On the other hand, the similarity of the thick epithelial cells in the tubules to those found in other glands led him to believe that the tubules have a secretory function. In short, he postulated that the urinary products, such as urea, are secreted by the tubules, and that the fluid formed in the glomeruli serves only to carry away the secreted materials.

Ludwig's Mechanical Theory.—Only two years after the publication of Bowman's paper, Carl Ludwig[84, 86] brought out the so-called "mechanical theory" by which he attempted to explain urine formation on a purely physical basis. According to this theory the hydrostatic pressure in the glomerular capillaries causes filtration of a large amount of dilute fluid containing all the urinary constituents; during its passage down the tubules, this fluid is concentrated by the diffusion of water into the tubular capillaries, the latter process being the result of a difference in osmotic pressure between the tubular fluid and the blood. Hoppe-Seyler later proved that this explanation of the reabsorption was indequate by showing that the osmotic pressure of the urine may be considerably higher than that of the blood leaving the kidney. Nevertheless, a large body of evidence was collected, mostly by Ludwig and his pupils, which demonstrated that urine flow was dependent on physical forces.[20] It was found, for example, that lowering of either the general blood pressure (e.g., by stimulation of the vagus in the neck, or by bleeding) or the renal blood pressure alone (partial occlusion of the renal artery) always reduced the urine flow. The same result was obtained by raising the ureteral pressure which at 50-60 mm. of Hg stopped urine secretion completely. On the other hand, the urine flow was augmented by raising the blood pressure with generalized vasoconstriction (provided the renal nerves were severed!) or with intravenous injections. The effect of partial occlusion of the renal vein did not, however, fall into line with the physical theory; instead of increasing the urine flow as one would expect (back pressure should tend to raise the glomerular capillary pressure, and therefore enhance filtration), this procedure accomplished quite the opposite.[63]

Heidenhain's "Secretion" Theory.—The mechanical theory of Ludwig was vigorously opposed by Heidenhain,[63] who formulated instead a "secretory" theory which was essentially an elaboration of Bowman's concept. According to Heidenhain, all constituents of the urine are formed by "vital" activity of the cells. The glomerulus secretes water and salt and the tubules secrete special urinous products, such as urea, and may also when required secrete water. Reabsorption in the tubules is completely excluded. Heidenhain's experimental evidence was drawn chiefly from a study of the secretion of dyes. One of his oft-mentioned experiments consisted of showing that indigo carmine is secreted by the proximal tubules of the rabbit when the blood pressure is so low that urine flow has ceased entirely. Under these conditions it was assumed that the dye could not have entered the tubules through the glomerulus since the latter was presumably nonfunctional. The interpretations which he placed upon his results were not universally accepted, and certainly the above experiment provides less convincing proof of secretion than that established by other methods to be described presently. Furthermore, even if the tubules do secrete a foreign

dye, it does not necessarily follow that they deal with normal constituents of the urine in the same manner. One of Heidenhain's chief objections to the mechanical theory was that it called for the filtration of what he regarded as unreasonably large amounts of fluid in order to account for the quantity of urea excreted. He pointed out that if the concentration of urea in the glomerular filtrate is 0.05 per cent, the daily excretion 35 grams and the urine volume 2 liters, then the mechanical theory requires the filtration of 70 liters and the reabsorption of 68. Now as a matter of fact, this is a rather low estimate (see below) and, furthermore, direct collection of capsular fluid from the individual glomerulus of the frog (Richards) shows that it is entirely within reason. Heidenhain also argued that the effect of obstructing the renal vein was a clear indication that blood flow and not blood pressure is the determining factor in regulating urine formation. Regarding the kidney as a true secretory gland similar to the submaxillary, he chose to interpret the results of Ludwig's experiments relating blood pressure to urine flow as being merely the effects of changes in the blood flow on the supply of oxygen and other nutrients to the secreting cells. Thus it would seem that although Heidenhain brought forth relatively little direct evidence in support of his secretory theory, his criticisms put the mechanical theory on the defensive.

That urine formation is not strictly comparable to the process of secretion in the salivary glands is evident from the following: (1) The submaxillary gland secretes only when stimulated through its nerves or by appropriate chemical stimuli (e.g., pilocarpine). When its connections with the central nervous system are severed, secretion stops. The kidney is in this respect quite different since stimulation of the renal nerves is unnecessary for its activity. Furthermore, it continues to secrete after complete denervation. (2) It was shown many years ago by Ludwig[85] that stimulation of the chorda tympani results in a secretion of saliva even when the blood pressure is zero. This phenomenon cannot be reproduced in the kidney. (3) Still more striking is the difference revealed by the maximal secretion pressures which the glands can produce. In the submaxillary gland this may be from two to three times greater than the existing arterial blood pressure,[85] whereas in the kidney it rarely exceeds one-half the blood pressure.[134] (4) The response of the submaxillary gland to a uniform stimulus is uninfluenced by dilution or concentration of the blood within the physiological range. The kidney, on the other hand, is remarkably sensitive to such changes. (5) The submaxillary gland secretes special substances (mucin, etc.) which are not found in the plasma. In contrast to this, the urine contains no special substance which is not also present in the blood. (6) Saliva is always more dilute with respect to crystalloids than the plasma from which it is derived. The concentration of the urine is not fixed with relation to the blood but may be either higher or lower, according to the requirements.

It is also instructive to compare urine formation with lymph formation, which, so far as we know, is a purely mechanical filtration process. (1) Nerve stimulation affects both urine and lymph flow only so far as it causes vascular changes. (2) The maximal secretion pressure is in both cases less than the arterial blood pressure. (3) All the constituents in lymph and urine may be found as such in the plasma. (4) A significant difference appears, however, if one compares the relative concentration of various substances in these fluids

with the relative concentrations in the plasma. The composition of lymph is in every respect similar to that of plasma except that it contains less protein.* In the urine, however, some of the plasma constituents are present in a much lower concentration than in plasma or may be entirely absent (e.g., glucose), whereas others (e.g., creatinine) may be raised to one hundred times their value in plasma. In view of these facts it is obvious that although urine formation resembles both salivary secretion and lymph formation in certain particulars, it cannot be relegated entirely to one category or the other. A complete theory of kidney function must include some features from both.

Cushny's "Modern" Theory.—A compromise is found in the so-called modern theory of Cushny.[20] This theory incorporates filtration of a protein-free fluid in the glomerulus and selective reabsorption in the tubules. The latter process is not explained by passive diffusion as in Ludwig's theory, but as an active process depending upon work done by the tubule cells. It should be noted also that the modern theory as formulated by Cushny excludes secretion, but evidence brought forth in recent years has required its inclusion at least for the excretion of certain substances, notably phenol red. The outstanding feature of the modern theory is that it attempts to simplify the process of reabsorption. Cushny noted that the tendency for a substance to be excreted by the kidney is roughly inversely proportional to its importance as a constituent of a normal perfusion fluid. This may be seen in Table CXX which gives the usual concentrations of a number of substances in plasma and urine. Substances such

TABLE CXX

as sulfate, creatine, urea and ammonia, which may be classed as waste substances, are evidently concentrated in the kidney to a great extent, whereas the necessary constituents of the plasma, such as glucose and sodium chloride, are either present in the urine in low concentration relative to their plasma levels or are entirely absent. On the other hand, if the latter substances, of which we may take glucose as an example, are present in the plasma in excess of their normal concentrations (i.e., above a certain "threshold" value), they are excreted. From these facts Cushny evolved the idea that the concentration in

*There is a slight difference in the electrolyte distribution due to the Donnan equilibrium.

which various useful substances are reabsorbed by the tubule cells has a definite limit, fixed for each substance according to the concentration at which it is present in a "normal" plasma. The substances that behave in this manner he called "threshold substances," and the remainder, which the tubule cells reject altogether, he called "no-threshold" substances. Thus he conceived of the reabsorption process as a blind process and urine as the inevitable result of the changes wrought in the capsular fluid by abstraction from it of a Ringer-Locke solution.

The data presented in Table CXXI will serve to show how he arrived at this conclusion. If it be assumed that all substances in the urine are derived only from the glomerular filtrate, and further that at least one substance in the filtrate is not reabsorbed by the tubules, the composition of the reabsorbed fluid may be calculated. Cushny took it for granted that sulfate is a strictly no-threshold substance. Therefore, on the basis of the plasma concentration of sulfate, he estimated that the amount present in 1 liter of urine must have been

TABLE CXXI

obtained from 90 liters of plasma or, that is, from 83 liters of protein-free filtrate. The amounts of the various constituents in this filtrate are known from their plasma concentrations, and by subtracting from these amounts the quantity excreted in 1 liter of urine, he derived the composition of the 82 liters which have been reabsorbed. Except that this fluid contains some urea and uric acid, its composition is very similar to that of a Ringer-Locke solution.

On first sight this seems to be an attractive simplification of tubular activity since it makes the kidney an organ with a fixed and predictable function. It does not, however, explain the actual mechanism whereby the tubule cells transfer substances against concentration gradients any more than did the secretion theory of Heidenhain. As a working hypothesis Cushny's theory has undoubtedly been of great service, but it should be pointed out that the investigations of the past decade have shown the theory to be incorrect in several respects. The reabsorption of water, glucose, chloride, phosphate and other substances are relatively independent processes, and several of the waste products which Cushny regarded as no-threshold substances are in reality partially reabsorbed. Furthermore, tubular excretion of certain substances can no longer be denied.

In view of these facts, it is a hopeless task at present to attempt to explain urine formation by any particular theory of renal function. Rather must we examine the facts and remain agnostic when these facts fail to provide a clear-cut explanation of the mechanism involved.

2. Function of the Glomerulus

We have already noted that Ludwig and his school demonstrated in a variety of ways that the rate of urine flow varies as the renal blood pressure. Viewed strictly, their evidence does not actually prove the existence of a filtration process in the kidney, much less that filtration occurs specifically in the glomerulus. These were suppositions based on the structure of the glomerulus, and it was a long time before unequivocal proof could be adduced to place glomerular filtration beyond cavil. The weakness in Ludwig's experiments lay in the fact emphasized by Heidenhain[63] that blood pressure and blood flow go hand in hand; that the changes in blood flow rather than the changes in blood pressure might be responsible for the observed variations in the rate of urine formation. Partial occlusion of the renal vein seemed to constitute a crucial test, for in this case the glomerular capillary pressure would rise while the blood flow would fall. The resulting decrease in the rate of urine formation was interpreted by Heidenhain to be clear proof that blood flow was the important factor. Ludwig, on the other hand, maintained that the engorged renal veins pressed upon the tubules to such an extent that the back pressure in the capsular fluid counterbalanced the effect of an increased glomerular pressure. After a period of controversy lasting nearly forty years, the question was finally settled in 1922 by the experiments of Richards and Plant.[108] A rabbit's kidney was perfused from a pump which kept the blood flow constant in spite of changes in the renal blood pressure. Under these conditions partial occlusion of the renal vein caused the urine flow to accelerate. This observation was confirmed by Dreyer and Verney[24] on the isolated dog's kidney. Recently Winton[148, 149] has devised a simple experiment which demonstrates in a direct manner that Ludwig's original interpretation of the effect produced by venous obstruction is correct. The intraureteral pressure is first raised by making the kidney secrete against a column of fluid. This in itself reduces the urine flow; but if the venous pressure is now increased, more urine is formed, provided the venous pressure does not exceed the ureteral pressure. Furthermore, if the ureteral pressure is gradually raised when the urine flow has already been reduced by partial obstruction of the vein, there is no further reduction in urine flow until the ureteral pressure exceeds the venous pressure. These experiments demonstrate in no uncertain fashion that physical forces are of fundamental importance in the formation of urine.

Glomerular Filtration.—According to the modern theory as enunciated by Cushny, the glomerulus forms a protein-free fluid by the simple process of filtration. Positive proof that this is the case requires the experimental demonstration (1) that the glomerular membrane is impermeable to the plasma proteins, (2) that the capsular fluid is in every respect identical with an ultrafiltrate of plasma, and (3) that the forces acting across the glomerular membrane are adequate to account for the formation of a protein-free capsular fluid. Through the efforts of Professor A. N. Richards and his colleagues, who have developed delicate micromethods for collecting (see Fig. 379) and

analyzing the capsular fluid from frogs, complete proof of glomerular filtration in the amphibia is now available. Their results will be considered before reviewing the less direct evidence for glomerular filtration in the mammal.

Glomerular Filtration in the Frog.—The semipermeable nature of the glomerular membrane of the frog was first demonstrated directly by Wearn and Richards.[144] They found that the capsular fluid normally is not only protein-free but contains glucose and chloride in approximately the same concentrations as the plasma. Since the latter was found to be true even when the bladder urine contained no glucose or chloride, the experiments also demonstrated that both of these substances may be reabsorbed by the tubules. In a series of investigations, which for their sheer elegance can hardly be rivaled in renal physiology, Richards and his co-workers have extended these observations to show that the composition of the capsular fluid is essentially identical with an ultrafiltrate of the plasma. Comparisons have been made on the basis of

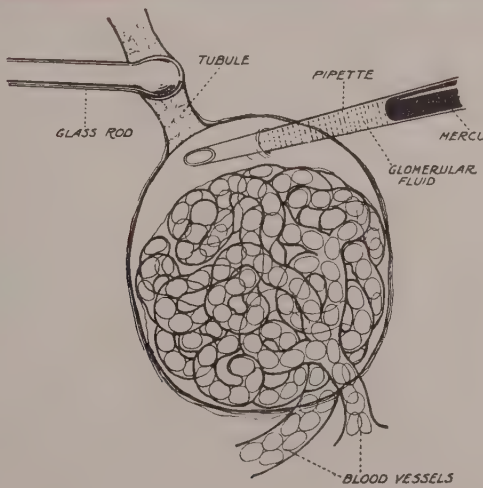

Fig. 379.—Diagrammatic representation of Richards' method of obtaining a sample of glomerular fluid from Bowman's capsule in the frog. A very fine pipette (7 to 15 μ diam.), connected with a reservoir of mercury and filled with mercury up to its tip, is thrust through the wall of the capsule, and fluid is withdrawn from the capsular space by lowering the mercury reservoir. The tubule is blocked by pressing on it with a fine glass rod, so that no fluid can be sucked back into the capsule. (From Winton and Bayliss.[121])

total molecular concentration (determined by Barger's vapor pressure method), electrical conductivity, chloride, inorganic phosphate, glucose, uric acid, creatinine and urea.[110] Experiments have also been made with phenol red and inulin. The only differences between the capsular fluid and plasma collected simultaneously were found in the analyses of chloride and phenol red. The former is slightly higher in the capsular fluid, but this is in accord with the Donnan equilibrium. In the case of phenol red, the unequal distribution is explained by the fact that about 30 per cent of this dye is combined with plasma proteins and is therefore unable to diffuse into the capsular fluid. The diffusible fraction, however, distributes itself in equal concentration between plasma and capsular fluid. The observations on inulin are of especial importance since

the capacity of the glomerular membrane to let this substance through is a fundamental assumption on which much of the experimental work on the mammalian kidney rests (see page 1118). In spite of its large molecular weight (5000), inulin distributes itself in the same concentration between blood and capsular fluid. In the face of such an impressive volume of evidence, it is impossible to avoid the conclusion that the frog's glomerular urine is merely a filtrate of plasma. There is no indication whatever that the glomerulus is capable of carrying out active secretion.

The forces concerned in the formation of capsular fluid in the frog have also been measured. In this species the plasma colloid osmotic pressure varies a good deal, the average being about 5 cm. of water. Is the glomerular capillary pressure sufficient to overcome this osmotic pressure? The measurements made by Hayman[62] indicate that the hydrostatic pressure is more than adequate to effect filtration. This may be seen in Table CXXII which represents a summary of Hayman's data.

TABLE CXXII

PRESSURES DETERMINING FILTRATION IN THE GLOMERULUS OF THE FROG'S KIDNEY

	PRESSURES (IN CM. H_2O)	
	RANGE	AVERAGE
Glomerular capillary blood pressure	10.0 to 27.0	20.2
Plasma colloid osmotic pressure (Churchill, Nakasawa and Drinker)	1.5 to 13.4	5.3
Filtration pressure	8.5 to 13.6	14.9

Hayman's technique was in principle similar to the cuff method of estimating blood pressure in man, and may be described briefly. A sharp-pointed micropipette was inserted into Bowman's capsule and connected with a manometer system (see Fig. 379). The neck of the proximal tubule was located by injecting colored saline, then closed with a glass rod. Thus the capsule served as a cuff in which the pressure required to occlude the capillaries could be measured. By this method the average glomerular capillary pressure was found to be 54 per cent of the existing aortic pressure.

The rate of filtration in individual glomeruli of the exposed kidney of the frog has been observed to vary from 1 to 3 or 4 c.mm. per hour. Each kidney in the frog contains some 2,000 glomeruli. Consequently, the total filtration rate in both kidneys of these animals is from 4 to 16 ml. per hour. Richards states that this is ten to twenty times greater than the urine flow. It is presumed that the rate of filtration is even higher in normal animals.

Glomerular Filtration in the Mammalian Kidney.—Unfortunately, the direct evidence obtained on the frog cannot be duplicated in the mammalian kidney because the glomeruli are located too far beneath the surface of the organ. There is, however, a sufficient amount of indirect evidence to indicate that the function of the glomerulus in warm-blooded animals is also purely a matter of filtration.

The limit of permeability of the mammalian glomerular membrane is defined with considerable sharpness by the recent experiments of Bayliss, Kerridge and Russell.[8] They followed the urinary excretion of a variety of proteins ranging in molecular weight from 35,000 (egg albumen) to 5,000,000 (hemocyanin) in anesthetized cats and rabbits and in the isolated dog's kidney. A summary of their observations is given in Table CXXIII. It is apparent from these data

that molecular size determines whether or not a protein escapes through the glomerulus. Hemoglobin, with a molecular weight of 68,000, appears to be on the borderline, since it is excreted only when present in the plasma in high concentration. The proximity of serum albumin to the limit of impermeability clearly explains why this serum protein is the first to appear in the urine when the kidney has been damaged temporarily by anoxemia, or permanently by renal disease. It was also noted by these investigators that the normal impermeability of the isolated dog's kidney to serum albumin was not altered or impaired by a period of perfusion with a protein, such as egg albumen which passes through the glomerulus. In view of these facts it must be concluded that capsular fluid in the mammal is normally protein-free. Furthermore, the capsular fluid is probably identical with an ultrafiltrate of serum since it is unthinkable that any of the crystalloid constituents could be retained by a membrane that only discriminates against proteins on a basis of their molecular size.

TABLE CXXIII

RELATIONSHIP BETWEEN MOLECULAR WEIGHT OF PROTEINS AND THEIR ABILITY TO PASS THE GLOMERULUS (From Bayliss, Kerridge and Russell[8])

	MOLECULAR WEIGHT OF PROTEIN*
Proteins excreted:	
Gelatin	35,000
Bence-Jones	35,000
Egg albumen	34,500
Hemoglobin	68,000
Proteins not excreted:	
Hemoglobin	68,000
Serum albumin	67,500
Serum globulin	103,800
Edestin	208,000
Casein	188,000
Hemocyanin (Helix)	5,000,000

*Determined by ultracentrifugation method.

Experiments on the isolated dog's kidney in which tubular function has been suppressed either with cyanide or by cooling lend further support to the belief that the fluid formed in the glomerulus is essentially the same as protein-free plasma. Starling and Verney[135] observed that the addition of cyanide to blood pumped through the kidney caused an increase in the volume of urine secreted. The concentration of chloride in the urine rose, whereas the amount of sulfate and urea fell, in percentage as well as in terms of the total amount excreted. In fact, the composition of the urine resembled closely that of deproteinized plasma. Similar results have been obtained by Bickford and Winton[12] by cooling the kidney to between 3 and 13° C. The effect upon the volume and composition of the urine is shown in the accompanying graph (Fig. 380). In spite of the fact that cooling reduces the blood flow to about one-half its normal value, the urine flow is greatly increased, showing that the reabsorption of water by the tubules has to a considerable extent been abolished. The similarity of the chloride concentration in the urine and plasma suggests that here also the urine produced is merely a filtrate. This is further borne out by the fact that creatinine, which is normally concentrated by the kidney, likewise approaches its plasma level.

What evidence have we that the forces acting across the glomerular membrane are adequate to account for filtration? It was first pointed out by Starling[133] that the osmotic pressure of the blood is determined by the plasma proteins. Since the plasma colloid osmotic pressure in the mammal is equal to 25-30 mm. of Hg, the formation of a protein-free fluid in the capsule requires that the hydrostatic pressure in the glomerular capillaries must at least exceed this figure. In addition, the pressure must be adequate to overcome the resistance to flow in the tubules. Winton estimates that the back pressure here is normally about 10 mm. of Hg. The filtration pressure is therefore equal to

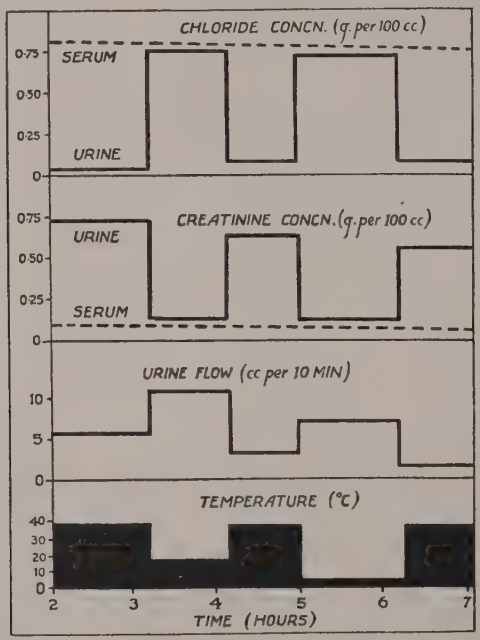

Fig. 380.—Diagram showing the influence of temperature on the isolated kidney of the dog. Cooling produces an increase of urine flow, and a change in its composition such that it has practically the same concentration of creatinine and chloride as serum. The effects are reversible. (After Bickford and Winton from Winton and Bayliss.[151])

the glomerular capillary pressure minus the colloid osmotic pressure and the pressure in the capsule, or, expressed in the form of an equation:

$$P_f = P_g - (P_{op} + P_c)$$

in which P_c is the pressure of the capsular fluid, P_{op} is the colloid osmotic pressure of the plasma, P_g is the glomerular capillary pressure, and P_f is the filtration pressure. By raising the ureteral pressure or lowering the blood pressure to a point where urine flow ceases (in which case $P_f = 0$), it is possible to arrive at a rough estimate of the glomerular capillary pressure and hence of the filtration pressure.

The ureteral pressure required to stop urine flow has been determined by a number of investigators. Figures as low as 10 and as high as 64 mm. of Hg

have been reported, but the usual value is 40 mm. of Hg. Adding to this the colloid osmotic pressure, which we may assume to be 25 mm. of Hg, it follows that the hydrostatic pressure in the glomerular capillaries must be about 65 mm. of Hg; in other words, somewhat more than half the arterial blood pressure. The ratio of the glomerular capillary pressure to the arterial pressure can also be determined by reducing the latter to the point where urine flow is suppressed. In the dog and the rabbit, Ustimowitsch[136] found this to occur at a pressure of 40 mm. of Hg. His observation has been confirmed by many others, notably Starling.[134] Winton,[149] however, raises the objection that a number of these experiments were carried out on kidneys secreting under the influence of large doses of diuretics. Even in the isolated kidney, in which reflex vasomotor effects are excluded, he finds that the urine flow usually stops when the arterial pressure is lowered to only 75 mm. of Hg. Nevertheless, if, for the sake of discussion, we assume that the minimum pressure is 50 mm. of Hg, we see again that the glomerular capillary pressure must stand at a little over half the arterial blood pressure. If this relationship holds when the

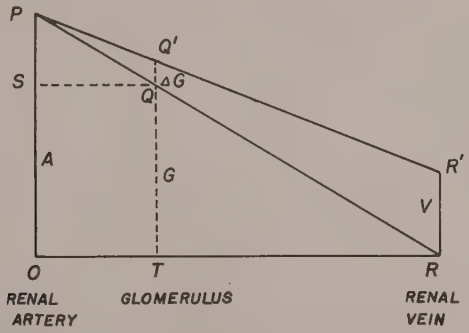

Fig. 381.—Diagram illustrating the relations between the arterial, glomerular, and venous pressures in the kidney. Ordinates, blood pressure. Abscissae, an irregular anatomical scale extending from the renal artery (*O*) to the renal vein (*R*); the intermediate points are defined by the condition that the blood pressure at any point lies on the straight line *PR*. (Redrawn from Winton.[149])

arterial pressure is normal, the glomerular capillary pressure is then between 60 and 70 mm. of Hg. In comparison with determinations of capillary pressure in other parts of the body, these figures are very high, but this is to be expected since the peripheral resistance in the kidney is principally in the efferent arterioles, whereas in the rest of the body the capillaries are placed beyond the peripheral resistance. Furthermore, our estimates agree quite well with Hayman's direct observations[62] on the frog, in which he found the glomerular pressure to be 54 per cent of the aortic pressure.

The glomerular capillary pressure in the heart-lung-kidney preparation of the dog has been calculated by Winton[149] from the equation:

$$\frac{\text{Glomerular pressure}}{\text{Arterial pressure}} = \frac{\text{Ureteral pressure}}{\text{Venous pressure}}$$

where the ureteral and venous pressures are so chosen that they cause the same reduction in the urine flow. Their values may be determined on a heart-lung-double-kidney preparation

if the urine flows from the two kidneys are initially the same. In one kidney the urine flow is then reduced by raising the venous pressure and the effect matched in the other kidney by raising the ureteral pressure.

The derivation of the equation and the assumptions on which it is based can best be understood from the diagram, Fig. 381. It is assumed that the pressure-fall from the renal artery O to the renal vein R follows the straight line PR. If the pressure in the renal artery remains the same when the venous pressure is raised from R to R′ (V), the pressures at various points in the system are then defined by the line PR′. That is to say, at any point in the system the increase in pressure caused by raising the venous pressure is proportional to the difference between the original pressure at that point and the arterial pressure. If T defines the position of the glomerulus on the horizontal scale OR, the glomerular pressure is initially QT. After raising the venous pressure it is Q′T. Since the triangles PQQ′ and PRR′ are similar, it follows that

$$\frac{QQ'}{RR'} = \frac{PQ}{PR}$$

Furthermore, by the similar triangles PQS and PRO it also follows that

$$\frac{PQ}{PR} = \frac{PS}{PO}$$

therefore,

$$\frac{QQ'}{RR'} = \frac{PS}{PO}$$

or

$$\frac{\Delta G}{V} = \frac{A - G}{A} \qquad (1)$$

where V is the increase in venous pressure, ΔG the increase in glomerular pressure, A the arterial pressure, and G the original glomerular pressure.

The rise in glomerular pressure ΔG is also related to the venous and ureteral pressures required to bring about the same decrease in urine flow.[148] This follows since an increase in the venous pressure has two effects which tend to alter the urine flow in opposite directions. The pressure in the vein is transmitted to the tubules and therefore raises the ureteral pressure; but the reduction in urine flow which would be produced by the latter is overcome to some extent by a concomitant increase in the glomerular pressure. Therefore the venous pressure V, which will cause the same reduction in urine flow as a given ureteral pressure U, must be higher than the latter by an amount which is equal to the increase in glomerular pressure. Thus,

$$\Delta G = V - U$$

Substituting for ΔG in (1) we have

$$\frac{V - U}{V} = \frac{A - G}{A}$$

or

$$\frac{U}{V} = \frac{G}{A}$$

The validity of this equation for calculating the glomerular pressure is indicated by the fact that under a constant arterial pressure the ratio of the ureteral and venous pressures required to cause the same reduction in urine flow is constant and independent of the absolute rate of flow at which the equivalent values of U and V are determined.

Utilizing this method of calculation, Winton[149] found the glomerular capillary pressure in the heart-lung-kidney preparation of the dog to be 65-75 per cent of the arterial pressure. With arterial pressures from 100 to 120 mm. Hg, the glomerular pressure ranged from 60 to 89 mm. Hg. We may conclude from these observations that the pressure-head in the glomerulus is adequate to overcome the colloid osmotic pressure of the plasma by a wide margin.

Recent evidence, however, suggests that there are other forces of considerable size which may oppose filtration. In this connection the reader should consult Winton's review on the *Physical Factors Involved in the Activities of the Mammalian Kidney.*[150] He points out that the diuresis produced by injection of saline is far greater (tenfold) than can be accounted for on the basis of the increase in the filtration pressure resulting from the dilution of the plasma proteins and the rise in blood pressure. Since saline has relatively little effect in the cooled kidney (tubular function suppressed), he is inclined to believe that its principal action is on the tubules. From the filtration surface in the glomerulus and the rate at which the filtrate is formed, it has been estimated that the pressure necessary to drive the fluid across the glomerular membrane is about 60 mm. Hg. It has also been estimated on theoretical grounds that the pressure required to drive the filtrate down the tubules may be equally large (25-80 mm. Hg); but judging from the height to which ureteral pressure may be raised without affecting the rate of urine flow, the back pressure in the tubules is only 10 mm. Hg. This back pressure is due to the intrarenal tension which is transmitted to the tubules. Since the kidney is enclosed in a nonelastic capsule, it is clear that swelling and shrinking of the renal tissue may have a considerable effect on the readiness with which urine escapes from the tubules, hence the anuria of certain types of edema and of the toxemias of pregnancy. As a last resort in these conditions, decapsulation of the kidney has been practiced, sometimes with beneficial results. The effect of changes in the intrarenal pressure also affords an explanation for the paradoxical increase in urine flow that results when a portion of the kidney substance is removed, or when one or two of the large branches of the renal artery are ligated.[150] Winton has demonstrated that the intrarenal pressure in this so-called "reduced kidney" is approximately one-half as great as in the intact kidney. It is evident from these observations that the intrarenal pressure must be regarded as one of the important factors which regulate urine flow both in health and in disease.

3. Tubular Function

If glomerular filtration is an established fact, it follows at once from the analyses of plasma and urine that the tubules must reabsorb at least some of the constituents (glucose and chloride) in the glomerular filtrate. Whether or not water is also reabsorbed is not so certain since the high urine concentration of such substances as creatinine and urea might equally well be explained by tubular excretion of these substances. The decision between reabsorption and excretion in the tubules can only be made when the volume of the glomerular filtrate is known. For the answer to these questions we must again turn first to experiments on the frog.

Tubular Function in the Amphibia.—Direct information on this question has been obtained by Richards and his co-workers from analysis of normal fluid collected at various points along the tubules and by observing the changes in the volume and composition of fluids perfused through isolated tubular segments.[110]

The technique presents certain difficulties because of the winding course of the tubules. The exact location of a puncture was determined after each experiment by injecting the tubule with India ink and immediately excising the entire nephron. In order to avoid the withdrawal

of fluid distal to the puncture, a small globule of mercury or oil colored with dye was injected into the lumen in such a way as to obstruct it distally. Sections of the tubules to be perfused were likewise isolated at both ends with globules of mercury. The perfusion fluid was then introduced into the lumen at one end of the segment and withdrawn at the other.

That the proximal tubule absorbs water is indicated by the fact that less fluid can be collected from the distal end of the proximal tubule than from the capsule. If Ringer's fluid is perfused through the lumen of the tubule at approximately the same rate as that provided by glomerular filtration, the amount collected is also less than the amount introduced. Furthermore, if glomerular filtration is abolished by blocking the capsule, it is impossible to obtain any fluid from the proximal tubule; consequently the proximal tubule does not excrete water under these conditions.

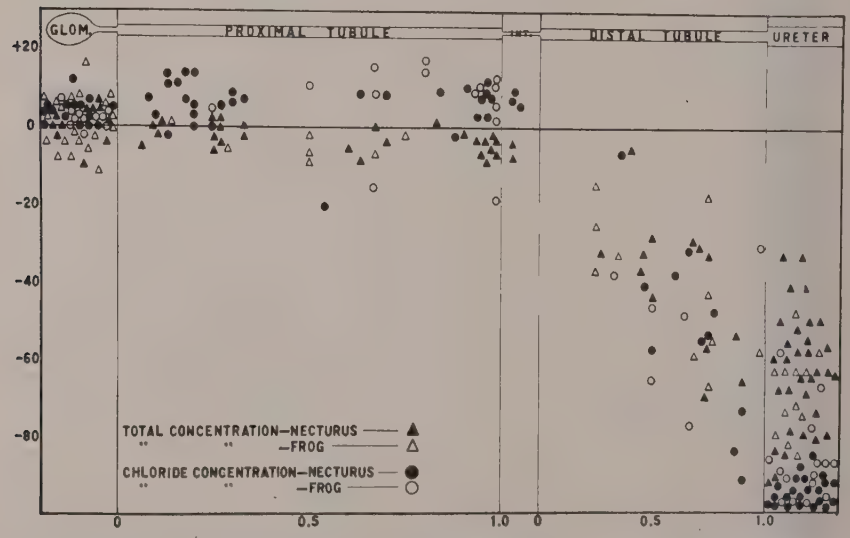

Fig. 382.—Chart showing differences between blood plasma and fluid collected from various levels of the renal tubules with respect to total concentration and Cl concentration. Sites of collection of tubule fluid can be identified by the points on the abscissa which represent fractions of the total length of the two chief segments of the tubule. Zero on the ordinate represents plasma. For chlorides, figures above and below represent percentage differences from plasma; for total concentration, they represent the micrometer scale divisions (each 5 μ) by which the 2 mm. capillary column of tubule fluid increased (+) or decreased (−) during forty-eight hours' equilibration against plasma. The representations of glomerular urine were taken from the previously published work of Walker[141] and Westfall, Findley and Richards.[147] (From Walker, Hudson, Findley and Richards.[148])

The results of chloride analyses on samples collected at various points along the tubule are shown in Fig. 382. This graph includes also determinations of the total molecular concentration. It will be seen that neither chloride nor total molecular concentration undergoes any significant change until the urine reaches the distal tubules; hence, the fluid which is absorbed in the proximal tubule must be essentially isotonic with the blood.

In contrast to the chloride, the glucose concentration in the glomerular filtrate falls rapidly after the fluid enters the proximal tubule (see Fig. 383). Perfusion of various parts of the tubules with Ringer's solution containing

glucose demonstrates that the reabsorption of glucose is limited to the proximal segment. In animals poisoned with phlorizin, on the other hand, the glucose concentration remains at or above the plasma level throughout the proximal tubule and appears in the ureter in high concentration. Consequently, the glycosuria produced by phlorizin is clearly due to an inhibition of reabsorption. Phlorizin does not, however, prevent the passive diffusion of some of the glucose back into the blood stream. This was shown by perfusing the proximal tubule of the mud puppy (Necturus) with Ringer's solution containing glucose in a concentration higher than that in the blood. The recovered fluid contained from 15 to 20 per cent less sugar than the perfusion fluid. In the same manner it was also shown that the tubules are partially permeable to the foreign sugar xylose.

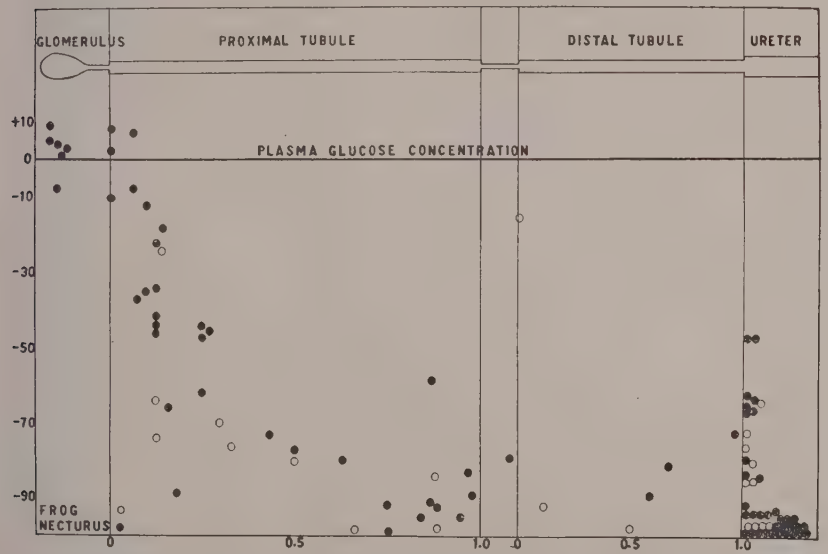

Fig. 383.—Chart showing differences in glucose concentration between blood plasma and fluid collected from various levels of the renal tubules of normal Necturi and frogs. Sites of collection of tubule fluid can be identified by the points on the abscissa which represent fractions of the total length of the two chief segments of the tubule. Zero on the ordinate represents plasma, figures above and below zero represent percentage differences from plasma. (From Walker and Hudson.[142])

Since the frog takes in large quantities of water through the skin, it must secrete a very dilute urine in order to preserve the normal concentration of salts in its body fluids. As shown in Fig. 382, this is accomplished by the reabsorption of sodium chloride in the distal tubule. This segment also reabsorbs sodium bicarbonate, for the urine suddenly changes from alkaline to acid in the last portion of the distal tubule (see Fig. 384). Furthermore, the distal segment is largely responsible for the reabsorption of water. This can be seen from the fact that after giving phlorizin, the concentration ratio (i.e., $\frac{\text{concentration in urine}}{\text{concentration in plasma}}$) of glucose in the tubular urine increases rapidly in

the distal tubule, finally reaching a value of 2.5. Richards estimates that only one-fifth of the total fluid reabsorbed is removed by the proximal tubules.

These experiments provide unquestionable evidence for tubular reabsorption and indicate furthermore that it consists of several independent and definitely localized processes. The next question to consider is whether or not tubular function is limited to reabsorption, and if not, to what extent tubular excretion contributes to the formation of urine.

Evidence for secretion in the tubules was brought forth by Nussbaum who took advantage of the opportunity presented by the double blood supply to the frog's kidney (see Fig. 378) for investigating tubular function independently. He found that although urine flow stops completely after ligation of the renal artery, it can be started afresh by injecting 1 to 1.5 ml. of 10 per

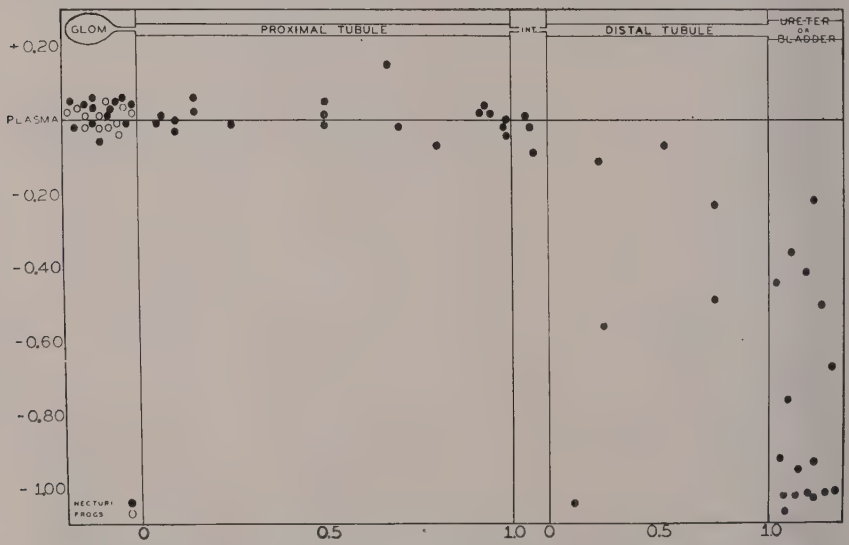

Fig. 384.—Reaction of glomerular urine in frogs and Necturi and of tubule urine in Necturi. Ordinates represent differences between fluid from the nephron and plasma as fractions of a pH unit; abscissae represent levels of the nephron from which fluid was collected. (Constructed from the data of Montgomery,[97] and of Montgomery and Pierce.[98]

cent urea into the anterior abdominal vein. The dye indigo carmine is also excreted under these circumstances. In 1906 the experiment was altered by Cullis to permit the perfusion of the arterial and venous systems separately. When attempts were made to repeat Nussbaum's observations with different techniques, many investigators questioned that ligation of the renal artery effectively occluded the glomerular circulation. Bensley and Steen[11] have pointed out that such observations were not valid because the experiments were done either without due regard for the precautions observed by Nussbaum or under conditions that were not analogous to those existing in the kidney after simply ligating the renal artery. By direct observation they found, as did Nussbaum, that the circulation through the glomeruli is completely stopped after the ligation.

On the other hand, as stated above (page 1099), the afferent arteries of the glomeruli sometimes give off branches directly to the tubules, and the efferent arteries may empty into either the renal-portal vein or the tubular capillaries, thus leaving open the possibility of some glomerular circulation. It was shown by Richards and Walker[109] that perfusion of the renal-portal system with Ringer's solution containing dye resulted in the appearance of dye in the glomerular capillaries. The possibility of an extra-renal collateral circulation was noted by Kempton,[72] who observed that the glomeruli of the posterior pole of a kidney in which the arteries were ligated could be perfused from the aorta. The source of this collateral circulation was from one of the two divisions of the normal arterial supply to the ureters. He found that when these collaterals from the ureter as well as the renal artery were ligated, no urine was excreted even after the injection of urea.

More convincing in the light of the clearance studies to be discussed presently, are the experiments of Marshall and Crane.[91] They have shown that the efficiency of the normal frog's kidney for excreting urea and phenol red is greater at low than at high plasma concentrations of these substances. That is to say, the kidney extracts a larger proportion of the dye or urea from the blood passing through the kidney when these substances are present in low concentrations. Furthermore, at high plasma levels the amount excreted is roughly the same regardless of the amount present in the plasma. If the amount excreted in the urine were derived solely from the glomerular filtrate, the rate of excretion would be directly proportional to the plasma concentration.

Analyses of tubular fluid in the frog show that urea is secreted by this species, and show furthermore that the secretion occurs mainly in the distal convoluted tubules.[110] In phlorizinized frogs, the maximum concentration ratio of glucose is about 2.5; whereas in the case of urea it may go as high as 20 or 30, showing that the high concentration of urea in the distal convoluted tubules and in the bladder urine cannot be explained simply by the reabsorption of water from the glomerular filtrate. Or to put it differently, the amount of urea excreted by the glomeruli is only a small fraction of the total amount excreted by the kidney. It is a mistake to assume from these experiments that tubular excretion of urea occurs in all animals, for even in the mud puppy, another amphibian, the concentration ratio of urea is no greater than that of glucose in the phlorizinized animal. Furthermore, we shall have occasion to note that in man urea is reabsorbed by the tubules.

Ammonia formation, demonstrated in the mammalian kidney by Benedict and Nash,[10] has recently been directly proved in the amphibian kidney by Walker.[140] Analyses of fluid collected at various points along the tubule show that ammonia appears first in the distal segment. Furthermore ammonia excretion continues when the kidneys are perfused with a fluid containing neither ammonia nor any known ammonia precursor. Since frog kidney extracts do not contain appreciable amounts of ammonia, there can be no doubt that it must be formed from some precursor, urea or amino acids, present in the tubule cells.

Tubular Function in the Aglomerular Kidney.*—The aglomerular fish provide an opportunity for the separate study of tubular function which is superior to that afforded by the Nussbaum frog preparation, if only because the obser-

*A detailed account of the functions of the aglomerular kidney may be found in the summaries by E. K. Marshall[90] and Homer Smith.[121]

vations can be made without anesthesia or surgical intervention. It was pointed out earlier that the tubule of the aglomerular kidney is the homologue of the proximal segment of the mammalian nephron. The similarity in function of other homologous structures wherever they occur among vertebrates suggests that the proximal segment of the mammalian tubule possesses, at least potentially, the same functional characteristics as the aglomerular tubule. Investigations of the renal function in the goosefish, the toadfish, the pipefish and the sea horse show that the aglomerular kidney is capable of excreting water, creatine, creatinine, urea, uric acid, magnesium sulfate, potassium and chloride. It can also excrete certain foreign substances, such as iodide, thiosulfate, sulfocyanide and the dyes, indigo carmine, neutral red and phenol red. The specialized character of aglomerular function is revealed in the above species by their inability to excrete ferricyanide, glucose, xylose, sucrose and inulin, all of which can be excreted by the glomerular kidneys of closely related marine forms. Increasing the blood sugar level to 400 or 500 mg. per cent or poisoning with phlorizin, both of which cause profuse glycosuria in glomerular kidneys, still leaves the urine from the aglomerular kidney sugar-free. That the aglomerular kidney is a pure secretory organ is futher demonstrated by the fact that the maximum secretion pressure may exceed the dorsal aortic pressure, whereas in the glomerular kidney this is always lower than the blood pressure. Consequently, urine formation in the aglomerular tubule is accomplished by secretion, and it will be seen that this function is to a certain extent retained in the mammalian tubule.

Tubular Function in the Mammalian Kidney.—From the similarity in structure of the mammalian and the amphibian nephrons, it is reasonable to expect that urine formation in both involves approximately the same processes. We have sufficient evidence to be certain that the analogy holds so far as the glomerular function is concerned. But, to assume that the pattern of tubular function in the frog would be repeated in the mammal in every detail is, to say the least, hazardous, for we have seen that even in the mud puppy, a close relative of the frog, there is a marked difference with respect to the excretion of urea. Furthermore, the mammalian tubule shows, aside from its greater length and larger number of convolutions, an important structural difference in that it possesses a thin segment, the appearance of which in the animal scale coincides with the ability of the kidney to excrete hypertonic urine.

Granted that the glomerulus acts as a simple ultrafilter, it follows from the arguments put forth by Cushny in support of the modern theory that the tubules reabsorb at least those diffusible constituents in the plasma which are absent from the bladder urine. We have seen that this applies specifically to glucose and chloride. That the tubules also reabsorb water is demonstrated by the experiments of Starling and Verney[135] and of Bickford and Winton,[12] which were described in connection with glomerular filtration. Suppression of tubular function, either with cyanide or by cooling, results in the formation of a larger amount of more dilute urine. The effect of cooling constitutes particularly impressive evidence for reabsorption inasmuch as the increase in rate of urine flow occurs in spite of a large decrease in renal blood flow. In addition, the change is reversible, showing that the glomerular membrane is not damaged by lowering the temperature.

Convincing evidence for tubular excretion in the mammal has been obtained from experiments with phenol red. It will be remembered that this dye has a tendency to combine with the plasma proteins; dialysis through semipermeable membranes shows that only 25 to 30 per cent is freely diffusible. Marshall and Vickers[92] calculated that in the dog the amount of diffusible phenol red brought to the kidney is entirely inadequate to account for the rate of excretion of this substance, even if it is assumed that the renal blood flow is maximal and that all the plasma is filtered off in the glomerulus. This conclusion was fully confirmed by Sheehan's experiments[117] on the explanted kidney of the dog, in which the phenol red extraction ratio was determined from the difference in dye content of arterial blood and renal vein blood and from the rate of phenol red excretion. Sheehan and Southworth[118] have demonstrated that this dye is also excreted by the tubules in the rabbit.

4. Analysis of Renal Function From Plasma Clearances

During recent years, great progress has been made in the study of renal function by applying the concept of *plasma clearance*. This term may be defined as the volume of plasma cleared of a given substance per minute by the kidney or, more correctly, the volume of plasma which would be required to provide the amount of the substance excreted per minute. It is calculated from the simultaneous plasma and urine concentrations of the substance and from the volume of urine formed per minute. If P is the plasma concentration of the substance, U its urine concentration and V the rate of urine flow in milliliters per minute, the plasma clearance may be expressed as follows:

$$\text{Plasma clearance in ml. per min.} = \frac{U \times V}{P}$$

In other words, the plasma clearance of any substance is equal to its concentration ratio $\frac{U}{P}$ multiplied by the rate of urine flow.

The implications of this concept become clear if we return for a moment to consider Cushny's theory. According to Cushny, all substances present in the urine are derived from the glomerular filtrate; furthermore, certain substances which he called no-threshold substances are not reabsorbed in the tubules. If this hypothesis be accepted, then the plasma clearance of a true no-threshold substance is equal to the glomerular filtration rate, for if the substance is neither reabsorbed nor secreted by the tubules, the amount filtered through the glomerulus is equal to the amount recovered in the urine. Therefore, the quantity $U \times V$ must be equal to plasma concentration of the substance multiplied by the volume of glomerular filtrate in which it was contained.

The possibilities that develop from this reasoning are not difficult to visualize. If the glomerular filtration rate can be measured, we are at once in a position to evaluate quantitatively the part played by the glomeruli and the tubules in the excretion of any given constituent in the urine. Thus if the plasma clearance of a substance is greater than the glomerular filtration rate, we have evidence of tubular excretion; and if its clearance is less than the glomerular filtration rate, we can say that the substance is being reabsorbed. The fundamental problem is to find a substance, the clearance of which is equal to the glomerular filtration rate under all conditions. The search, led

chiefly by Homer Smith and his collaborators, constitutes one of the most illuminating chapters in renal physiology. The reader is urged to consult Smith's recent publications for a detailed account of this important subject.[129, 131]

A substance which is to be used for measuring glomerular filtration rate must satisfy a number of requirements. (1) It must diffuse freely through the glomerulus and therefore must not combine with the plasma proteins to which the glomerulus is impermeable. (2) It must not be excreted by the tubules. (3) It must not be reabsorbed in the tubules. (4) It must be physiologically inert, not only in the sense of being nontoxic, but especially with respect to its effect on renal function either directly or indirectly. (5) It must be a substance which can be determined accurately in plasma and urine.

Method of Determining Plasma Clearance.—If the substance under consideration is not a normal constituent of the plasma, or if its plasma level is too low to be accurately determined, it must be administered in suitable amounts and preferably at a uniform rate in order to maintain its plasma concentration at or near the same level during the period of the test. This can usually be accomplished most readily by giving a continuous intravenous injection preceded by a large priming dose. Blood and urine samples are collected at frequent intervals, particular care being taken to collect all the urine excreted during each period by washing out the bladder with a known volume of saline and expelling the last traces of fluid by insufflation with air. The volume of each urine sample is obtained by subtracting the volume of saline used for washing. In spite of these precautions some error may arise from the fact that an undetermined though probably small volume of urine remains in the tubules and the ureters. The results obtained from analysis of the plasma samples are then plotted against time and the plasma concentration at the midpoint of each period determined by interpolation of the time-concentration curve.

The measurement of glomerular filtration rate in man was first attempted by Rehberg.[107] He chose creatinine for this purpose, since among the normal urinary constituents it displays one of the highest concentration ratios (about 100), a fact which, according to Cushny's theory, would indicate that it is not reabsorbed by the tubules. Since Cushny's theory also denies the existence of tubular excretion, Rehberg assumed that the plasma clearance of creatinine is equal to the glomerular filtration rate. But, when it was subsequently shown that in man creatinine is actually excreted by the tubules, it became evident that Rehberg's results were founded on an insecure hypothesis.

In the search for substances not likely to be secreted by the mammalian tubule, valuable leads were obtained from the study of renal function in the aglomerular fish. It will be remembered that glycosuria cannot be induced in the aglomerular kidney either by raising the plasma concentration of glucose or by poisoning with phlorizin. Since phlorizin inhibits tubular reabsorption of glucose in the glomerular kidney, the glucose clearance in the phlorizinized animal should be equal to the glomerular filtration rate, and thus constitute a useful standard to test other substances for use in measuring the glomerular filtration rate in normal animals. Among the first substances tested were xylose, sucrose and raffinose. Tubular excretion of these foreign sugars by the mammalian kidney seemed improbable since it was found that they are not excreted by the aglomerular kidney. Tubular reabsorption was also unlikely since they were known to be eliminated rapidly by the normal mammalian kidney. These suppositions were confirmed by the fact that in the phlorizinized dog, the clearances of all three sugars are the same as that of glucose. Furthermore, their clearances are independent of their plasma concentrations. This fact also indicates that the tubules do not reabsorb or excrete these sugars, for in either case it is very improbable that active tubular processes would be closely adjusted to the plasma concentration. More recent work, however, has shown that their plasma clearances in the normal animal are not identical with the glomerular filtration rate because all three are partly reabsorbed in the tubules. According to Homer Smith, this reabsorption is associated in some way with the reabsorption of glucose and does not occur when the latter is prevented by phlorizin.

The Plasma Clearance of Inulin.—Recent evidence obtained independently by Richards and by Smith and their respective coworkers now points to inulin

as being a substance which under all conditions has a plasma clearance that is identical with the glomerular filtration rate.

Inulin is a polysaccharide with a molecular weight of about 5,000. It is subject to satisfactory chemical analysis and when injected intravenously is not metabolized but excreted quantitatively by the kidney. It produces no untoward symptoms in human subjects, and, so far as is known, has no effect upon the circulation or the renal function. That inulin is freely filtrable is shown by the fact that in the frog its concentration in the glomerular fluid is the same as in the plasma. It also diffuses freely through collodion membranes impermeable to the plasma proteins. It is not excreted by the aglomerular kidney, but is eliminated rapidly by the glomerular kidney. As in the case of xylose, the clearance is independent of its plasma concentration. Furthermore, in view of its large molecular weight, inulin does not, in all probability, diffuse out of the tubules. This is indicated by the fact that in the normal dog and in man (see Fig. 385) the inulin clearance is greater by about 25 per cent than the simultaneous clearances of xylose and sucrose, both of which are to some extent reabsorbed by the tubules. After phlorizin, the simultaneous clearances of xylose, sucrose, glucose and creatinine are identical with that of inulin. The agreement under these conditions is brought about by a large rise in the glucose clearance (active tubular reabsorption abolished), a smaller increase in the xylose and sucrose clearances (partial reabsorption abolished), and a drop in the creatinine clearance* (tubular excretion abolished). The clearance of inulin itself is unaffected by poisoning with phlorizin. As may be seen from Fig. 385, Smith maintains that the clearances of the polyhydric alcohols, sorbitol and mannitol, are identical with that of inulin.

These facts constitute strong evidence that the inulin clearance in the phlorizinized animal is equal to the glomerular filtration rate, for it is difficult to believe that tubular excretion and reabsorption would affect all substances in the same way. Furthermore, since phlorizin has no effect upon the inulin clearance, it follows that the latter must be identical with the glomerular filtration rate in the normal kidney. Thus by comparing the simultaneously determined clearances of other substances with that of inulin, it is possible to estimate the extent to which various urinary constituents and foreign substances are excreted or reabsorbed by the tubules.

In man the ratio, $\frac{\text{creatinine clearance}}{\text{inulin clearance}}$ is ordinarily about 1.40. Consequently, tubular excretion accounts for about 30 per cent of the total creatinine normally removed by the kidney; but if the plasma level is raised, this fraction excreted by the tubules is smaller (see Fig. 386). It has been suggested that the kidney distinguishes between endogenous and exogenous creatinine, the former being secreted by the tubules and the latter being filtered through the glomerulus. The question is still unsettled because the determination of creatinine in plasma may not be sufficiently specific to exclude other substances. In the dog, however, the creatinine and inulin clearances are identical, an indication that in this species creatinine is excreted by glomerular filtration only.

The manner in which urea and phenol red are handled by the kidney in man is of especial practical interest, as these substances have been used extensively for kidney function tests. Referring to Figs. 385 and 386, it may be seen that the normal urea/inulin clearance ratio is about 0.6, showing that approximately two-fifths of the urea cleared by the glomerulus is reabsorbed in the tubules. It is generally believed that this is due merely to passive diffusion, an explanation which Shannon[116] finds inadequate. Thus, if the standard urea clearance test yields a low value in renal disease, it might indicate either a diminished glomerular filtration rate or an increased permeability of

*This refers only to man. In the dog creatinine is not removed by tubular excretion.

the tubules. According to results obtained on the explanted kidney by Van Slyke, Rhoads, Hiller and Alving,[137] tubular permeability to urea may be temporarily increased even by physiological disturbances. The normal phenol red/inulin clearance ratios (compare their clearances in Fig. 386) show that in

man as well as in the dog the kidney removes phenol red chiefly by tubular excretion. Thus in comparison with the normal, the rate at which the diseased kidney excretes a standard amount of phenol red would be an index of the secretory capacity of the tubules, but not accurately so since some dye is also excreted by glomerular filtration. As the plasma level of phenol red is in-

creased, the tubular excretion reaches a maximum value. The determination of this maximum capacity of the kidneys to excrete the dye is proportional to the so-called "tubular excretory mass" and constitutes a quantitative method of estimating the extent of tubular damage.[116]

Glomerular Filtration Rate and Urine Flow.—It may be seen from Fig. 386 that the inulin clearance in man is about 120 ml. per minute. Since the urine flow is usually about 1 ml. per minute or 1.5 liters per day, it follows that tubular reabsorption goes on at the rate of 119 ml. per minute. Thus in twenty-four hours the kidneys filter about 170 liters of fluid and reabsorb 168 or 169 liters, containing 1,000 grams of sodium chloride, 360 grams of sodium bicarbonate and 170 grams of glucose. Since this is accomplished by some 2,000,000 secretory units, the rate of filtration in each glomerulus is about 0.001 c.mm. per second. With a filtration pressure of at least 50 mm. of Hg, the formation of this quantity of fluid does not seem to be an insurmountable task.

The glomerular filtration rate as measured by inulin clearance is remarkably constant in man. It can be altered by changes in the blood pressure and by vasomotor reflexes; but hydration or dehydration, unless driven to the extreme, appears to have little effect. Normally, therefore, the urine volume must be determined by the rate of tubular reabsorption. Even this process is subject to variation within relatively narrow limits. Inasmuch as the maximum urine flow does not exceed 20 ml. per minute, i.e., less than one-fifth of the glomerular filtration rate, it would seem that the reabsorption of at least four-fifths of the glomerular filtrate is a fixed process under all conditions, leaving the rest to be reabsorbed or not, in accordance with the demands for water conservation.

The constancy of the glomerular filtration rate is rather surprising in view of the fact that the arrangement of the blood vessels in the renal corpuscle is such that one would expect large fluctuations in the pressure and flow of blood in the glomerulus. But it may well be that reflex mechanisms exist which tend to keep them constant. This, however, is not in accord with direct observations on the frog in which the glomerular filtration rate varies greatly and the glomerular circulation shows a characteristic spontaneous intermittance. Under normal circumstances, only a small proportion of the glomeruli in the frog's kidney is active at one time, the activity shifting from one to the other. Also in the individual glomeruli, the circulation may change spontaneously, involving first one capillary loop, then another, or suddenly continuing through all. Thus, the filtration surface may be very different from time to time. It is decreased by hemorrhage or by application of adrenalin, and increased by the intravenous injection of saline or blood and by diuretics, such as urea and glucose. Variations such as these in the distribution of blood in the kidney should have pronounced effect on the rate of urine secretion, for if we consider ten individual secretory units in which the filtration surface may be altered tenfold by opening or closing the capillary loops, it is apparent that the quantity of fluid filtered must vary accordingly. Furthermore, given the same number of patent glomerular capillaries, and hence the same volume of filtrate, the final composition of the urine will obviously depend upon whether the filtrate is poured into a few tubules or distributed among a larger number.

Measurement of Renal Blood Flow With the Clearance Method.—From Fig. 386 which provides an instructive summary of the manner in which various

substances are excreted by the kidney, it may be seen that at low plasma levels the clearances range from zero, for glucose and vitamin C, to 400 ml. per minute for phenol red and to more than 700 ml. per minute for diodrast. The plasma is obviously cleared of diodrast with remarkable efficiency. The diagram furthermore shows that in the case of this substance the maximum clearance is reached at a plasma concentration of about 10 mg. per cent. What limits the increase in clearance with further reduction in the plasma level of diodrast? The answer appears to be that the upper limit of clearance values has been reached—that the kidneys are excreting all of the diodrast brought to them by the blood (100 per cent extraction). Under these circumstances the clearance is therefore equal to the milliliters of plasma flowing through the kidneys per minute, and if the hematocrit is known, one may calculate the total renal blood flow. Comparison of the diodrast concentrations in blood taken from the renal artery and vein shows that the extraction is practically complete. Other evidence of less direct nature also justifies the assumption that the diodrast clearance is essentially equivalent to the plasma flow.[129, 132] It should be added that Smith and his associates have employed the diodrast clearance method in a most fruitful study of the renal circulation in man.[130]

C. REGULATION OF RENAL FUNCTION

From the preceding discussion of the mechanism of urine formation, it may be seen that the renal function as a whole is subject to a multiplicity of influences. Principal among them are those changes in the general circulation which affect the pressure and flow of blood through the renal artery,[130] vascular adjustments within the kidney itself, and changes in the ureteral and intrarenal pressures, which in turn are influenced by the volume and pressure of the blood in the kidney. Thus, hemorrhage, and the vasomotor disturbances accompanying excitement, digestion, muscular activity, etc., may have marked effects on urine flow. The intra-abdominal pressure must also be considered. One is tempted to speculate on its possible connection with the sluggish response of the kidney to water ingestion during pregnancy.

All these circulatory disturbances and mechanical pressures influence kidney function by virtue of their effects on the glomerular filtration rate. It is doubtful whether normally they serve to integrate renal excretion with the bodily requirements, for the glomerulus as a filter does not act specifically to maintain the composition of the blood. The fine adjustment of renal function to disturbances in the latter is attributable to selective processes in the tubules.

It is hardly necessary to point out that the kidney is remarkably versatile and discriminating in its activity. For example, it is a matter of common experience that the excretion or retention of ingested water depends upon the state of hydration of the body. Yet whatever happens to the water, the concentration of the blood is hardly affected. We have seen that in the case of glucose, a sharp distinction is made by the kidney on the basis of the plasma concentration of this substance. Although the threshold for sodium chloride is less clearly defined, it is excreted or rejected in accordance with the bodily supply. Normally the intake of salt is in excess of the requirements, with the result that a considerable amount is usually excreted. But if salt has been lost in sweat or if the diet is deficient in sodium chloride, the amount in the urine

dwindles to very low levels. The kidney also plays an essential part in the maintenance of the hydrogen ion concentration of the blood. If there is a slight preponderance of anions in the body fluids, the urine becomes acid out of all proportion to the change in the blood. Considerable base is then conserved, since in an acid medium the urinary phosphate is excreted largely as a monobasic rather than as a dibasic salt. Furthermore, under these conditions the kidney may form larger amounts of ammonia with which the excess acid may be excreted without its usual complement of fixed base. On the other hand, when the body fluids contain an excess of fixed base, the formation of alkaline urine permits the excretion of phosphate as a dibasic salt. Also bicarbonate now supplants the chloride. Both processes result in the conservation of chloride, which would otherwise be required for the excretion of fixed base.[37] Aside from these and other essential constituents of the plasma, the kidney must also cope with a great variety of foreign substances and waste products which are presented for excretion in variable amounts. In all instances retention or excretion is determined by tubular activity. The glomerulus makes no distinction except on the basis of molecular weight; only the proteins and substances which are made nondiffusible by combination with them are held back by this part of the secretory unit.

Water Diuresis.—The ingestion of a moderate amount of water (1.0-1.5 liters) usually has a marked diuretic effect. The increase in urine flow is noticeable within twenty to thirty minutes; it rises to a maximum in one to two hours and subsides to the previous level in three to five hours. The volume of fluid excreted during this period is normally equal to or slightly greater than the volume ingested. The urine is pale in color and its specific gravity low, 1.002 as compared with the normal value of 1.020, showing that the excretion of water is not accompanied by an increase in the excretion of solutes. The response in this respect, however, is conditioned somewhat by the supply of salt in the body.

The well-recognized sensitivity of the kidney to changes in the composition of the blood led many investigators to seek the cause of water diuresis in blood dilution.[57, 111, 122] As a result, the literature now contains abundant data dealing with the effect of water ingestion on the water content of the blood as measured by the concentration of hemoglobin, plasma proteins, total solids and chloride, and by the conductivity of the serum. A survey of all these data shows that although hemoglobin and plasma proteins are usually diluted slightly, this change is by no means essential for the occurrence of diuresis. Using the method for measuring plasma volume described in Chapter LXXVIII (see Figs. 367 and 372), the author and his collaborators have found that water diuresis may occur without evidence of dilution of the dye injected prior to the experiment. This constitutes definite evidence that there is no increase in the total plasma volume, a fact which cannot be concluded from the hemoglobin or plasma protein determinations mentioned above, since the amount of these substances circulating in the blood may itself change.

The electrolytes are the only constituents of the blood which appear to be consistently affected by the ingestion of water. Careful determinations of total osmotic pressure of serum by Baldes and Smirk[5] (Hall's vapor pressure method) show that there is a decrease of between 1.5 and 2.75 per cent in the electrolyte concentration within thirty minutes after the ingestion of one liter

of water. It will be seen that this is precisely the dilution one would expect if the ingested fluid were distributed equally through all the water in the body (about 45 liters). Furthermore, the time (thirty minutes) required for the dilution to take place is a measure of the rate at which the water is absorbed from the gut. The rate of absorption has been determined with an attractively simple method devised by Smirk.[121] By placing the abdomen or the legs of the subject on weighing scales in a suitable manner, he found that after one liter of water had been ingested, the weight of the abdomen gradually decreased, whereas the weight of the legs increased. The change was complete within twenty-five to fifty-five minutes. The percentage increase in leg weight (1.15) corresponded closely with the dose of water (1.3 per cent of the body weight), again indicating that the fluid is distributed equally through all the water in the body. The change in electrolyte concentration does not, however, affect the kidney directly, for it has been found by Rioch[111] and confirmed by many others that there is a lag of some fifteen to twenty minutes in the diuresis. If the blood is diluted by injecting water intravenously the same lag occurs.[101] Furthermore, the absolute level of the plasma electrolyte appears to be of minor significance, as water diuresis may occur either when the plasma electrolyte concentration has been lowered by salt-deficient diets or sweating, or when it has been raised by increasing the salt intake.

It has long been suspected that renal excretion of water may be controlled by a hormone from the posterior lobe of the pituitary gland. The hormone was first thought to have a diuretic action when Magnus and Schäfer[87] found, many years ago, that extracts of the posterior lobe cause increased flow of urine in anesthetized animals. This, however, is attributable to a temporary circulatory disturbance and does not represent the specific renal effect of pituitrin which, on the contrary, is antidiuretic. The latter is demonstrated by the fact that pituitrin retards water diuresis for several hours in the normal unanesthetized animal, reduces the polyuria in diabetes insipidus and diminishes the urine flow in the isolated heart-lung-kidney preparation when added in minute amounts to the blood perfused through the kidney. It should be pointed out that pituitrin does not reduce the diuresis caused by salt or urea. Its action is limited to the urine water not required for the excretion of solutes.[3]

These observations and the experience that the polyuria of diabetes insipidus is associated with lesions in the vicinity of the hypophysis indicate that the renal output of water is regulated by the antidiuretic hormone from the posterior lobe. Seemingly in conflict with this view are the facts that complete removal of the pituitary gland does not consistently result in polyuria, that diabetes insipidus can be produced experimentally by hypothalamic puncture, and that the occurrence of the disease is not invariably associated with tumors that involve the posterior lobe directly. It might be assumed that the hormone acts upon nerve centers in the base of the brain and that in the absence of the pituitary these can still regulate the water output. But actually these possibilities are out of the question, since the antidiuretic effect of pituitrin is exerted upon the denervated or isolated perfused kidney as well as on the normally innervated kidney. Furthermore, denervation of the kidney neither abolishes polyuria nor interferes with its development in experimental diabetes insipidus. The recent investigations of Ranson and his co-workers[31, 32, 34, 35, 69, 70] have thrown much light on this confusing problem. For a summary of the

literature the reader should consult their reports. Using the Horsley-Clarke stereotaxic instrument, they were able to approach the hypothalamic region from above and to make sharply localized lesions in the hypothalamic nuclei and in the fiber tracts between these and the pituitary, without disturbing the pituitary itself. In cats and monkeys they found that polyuria was consistently produced by destruction bilaterally of the supraoptic nuclei, or of the fiber tracts leading from these to the posterior lobe. In animals thus treated the posterior lobe atrophies, and extracts made from four such glands in the cat showed little or no antidiuretic effect. The reports that polyuria is not produced after extirpation of the entire pituitary seem to be explained by incomplete removal of posterior lobe tissue lying along the stalk, and not by the claim recently put forth that the anterior lobe secretes a diuretic hormone. The diuretic effect of anterior lobe extracts appears to be related to changes in metabolism since it is said to depend upon the thyroid.

The view now generally accepted is that both normal water diuresis and the polyuria of diabetes insipidus are the result of a decrease in the amount of the antidiuretic hormone supplied to the kidney. That the hormone acts directly upon this organ is attested by the experiments on the isolated and denervated kidney, mentioned above. The antidiuretic effect is brought about by increased reabsorption in the thin segment of the tubule for, as Burgess, Harvey and Marshall[16] have shown, pituitrin does not retard water excretion in lower animals in which the thin segment is lacking (see Fig. 377). The existence of hormonal control of water excretion is indicated by the experiments of Klisiecki, Pickford, Rothschild and Verney[73] on dogs with exteriorized ureters and one kidney denervated. In this preparation the delay between increased water load of the body and diuresis is identical for both kidneys. Inhibition of water diuresis by afferent stimulation also affects the normal and denervated kidney equally. In this case too, the effect is not immediate but occurs after ten to fifteen minutes. It has also been reported that the injection of blood from a normal animal retards water diuresis, whereas no antidiuretic effect is observed after injection of blood obtained from animals during diuresis.[131] Gilman and Goodman[43] report that the antidiuretic hormone is excreted in the urine and that the amount excreted is related to the need of the organism for water conservation. They found that urine from dehydrated rats contains large amounts of antidiuretic substance which is entirely absent from the urine collected during water diuresis or after the animals have been hypophysectomized.

Diuretics.—The consideration of diuretics belongs more particularly to the province of pharmacology, since many of the substances included in this category may be classed as drugs. It is sufficient here merely to mention some of the ways in which these substances may promote the flow of urine.

By the term *diuretic* is usually meant a substance which, if injected in small amounts, increases the urine flow by specific renal effects. In many instances, however, this definition appears to be incorrect, for the analysis of the action of a number of diuretics shows that they exert their influence in part through the circulation and the central nervous system. The diuresis from caffeine, for example, may be the result of a diminished output of antidiuretic hormone, since caffeine is known to have a marked action on the nervous system. Within the kidney itself, diuretics may act by stimulating the glomerular circulation, as is the case with caffeine, or by hindering reabsorption in the tubules. The latter can be most simply explained as an osmotic effect resulting from the inability of the diuretics to diffuse through the tubular epithelium. Among the substances that behave in this manner are sulfate,

urea and sucrose. The diuresis which follows the ingestion of acidifying salts (e.g., NH_4Cl, and $CaCl_2$) is presumably the result of the disturbance in the acid-base equilibrium of the blood.

The Function of the Renal Nerves.—The presence of nerve fibers in and among the tubule cells suggests that there may be some specific neural control of tubular excretion and reabsorption, especially since the activities of true secretory cells in many other parts of the body are known to be regulated by the nervous system. According to the best authorities, however, the evidence which seems to indicate the existence of specific secretory nerve fibers in the kidney can be explained on the basis of changes brought about by the vasomotor nerves or by complicating experimental factors, such as anesthesia. We have already noted that the denervated kidney does not reveal any deficiencies in its finer adjustments to external influences or to the composition of the blood. For the present, then, it must be assumed that the action of the renal nerves on urine formation is limited to their effect on the pressure and flow of blood through the kidney.

CHAPTER LXXXIII

THE URINARY BLADDER

By Walter S. Root

The urinary bladder is an organ designed for the storage of fluid. Urine, formed in the kidney, is propelled down the ureters by rhythmic peristaltic waves and enters the bladder in spurts. Here, it is temporarily stored and periodically voided. The ureters, which traverse the bladder wall obliquely, are compressed easily by contractions of the detrusor muscle. This prevents reflux of urine as the intravesical pressure rises.

The bladder muscle exhibits two types of activity: sustained contraction or tonus, and intermittent contractions. The act of micturition demands the coordination of these common smooth muscle responses with sphincter activity, in which the intervention of the central nervous system is essential.

The Nervous Control of the Bladder

The Innervation of the Bladder and Urethra.—Most experimental investigations of bladder function have been carried out upon the cat. In this animal, the smooth muscle of the vesicle derives its sympathetic innervation from the lumbar splanchnic nerves which leave the spinal cord between the second and fourth lumbar segments (Fig. 387). Passing through the corresponding ganglia of the abdominal sympathetic chain, the majority of these fibers enter into synaptic relation with a second neuron in the inferior mesenteric ganglia. The postganglionic fibers run downward in the hypogastric nerves to supply the body and neck of the bladder. Parasympathetic fibers from the first three sacral segments unite on each side to form the pelvic nerve (nervus erigens). Sympathetic and parasympathetic nerves mingle in the hypogastric (pelvic) and vesical plexuses. The short postganglionic parasympathetic fibers, arising in the vesical ganglia, pass to the body and neck of the bladder. In the cat, the entire bladder neck serves as the internal sphincter. The striated compressor urethrae muscle, constituting the external sphincter, is innervated by the pudendal (pudic) nerves. It is commonly stated that the pudendal nerves emerge between the first and fourth sacral segments, although some authors[9] restrict their origin to the first two sacral roots.

Stimulation Experiments.—Attempts to study the function of the nerves supplying the bladder by stimulation experiments have yielded equivocal results. Indeed, it has been reported[11] that the responses depend upon the nature and the depth of the anesthesia, as well as upon the tonus of the detrusor muscle. More conclusive data have been obtained by the investigation of bladder reflexes in which it is possible to employ more natural stimuli.

Bladder Reflexes.—Barrington, who has studied the control of the feline bladder in considerable detail, distinguishes six bladder reflexes[1, 2, 3, 4] (see Table CXXIV). The following discussion is based upon his observations.

When the bladder of a lightly anesthetized[1] or a decerebrated cat[2] is distended with a moderate quantity of fluid, there is a transient rise in intra-

vesical pressure which decreases as the organ adapts its capacity to the changes in volume. As successive volumes of fluid are introduced, the curve of intravesical pressure shows a gradual steplike ascent. At a certain point in vesical filling, the detrusor muscle contracts, the bladder neck and the compressor urethrae muscle relax, and the contents of the bladder are expelled. Since changes in bladder capacity require some little time, the reflex may be elicited at

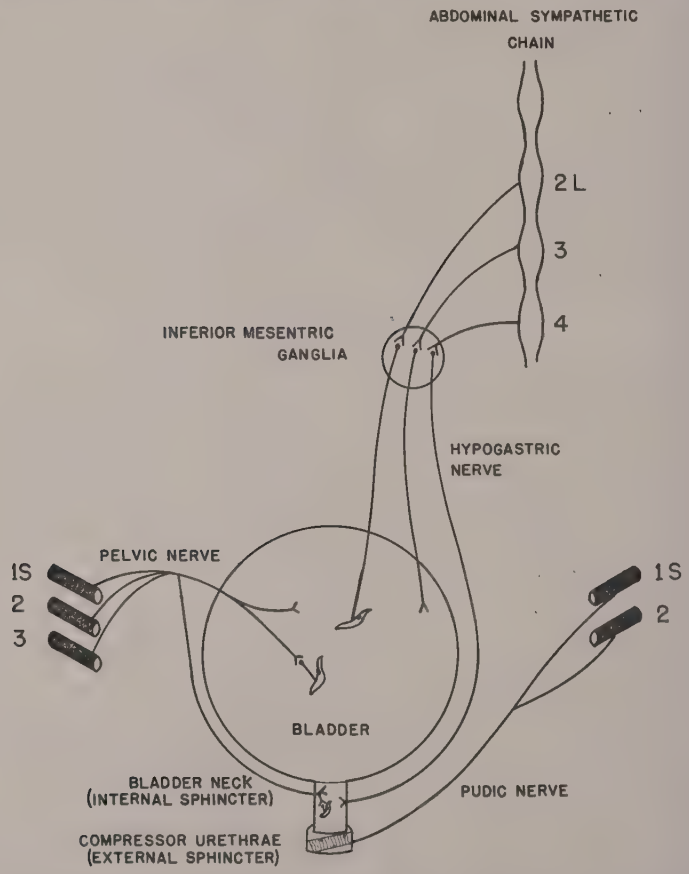

Fig. 387.—Diagrammatic representation of the innervation of the urinary bladder in the cat. (Modified from Learmonth.)

a lower volume than usual, if fluid is introduced rapidly. This finding indicates that intravesical pressure rather than intravesical volume initiates the reflex. Roentgenograms show that until the reflex occurs, fluid is held at the junction of the bladder and the posterior urethra. The responses of the human bladder are identical.[6]

The results of action current studies demonstrate that the afferent impulses, responsible for the detrusor reflex, arise from stretch receptors in the bladder

wall and enter the spinal cord by way of the pelvic nerves.[13] The tonic state of moderate contraction characteristic of the cat's bladder is associated with a constant outflow of pelvic impulses to the fundus and the bladder neck.[7] It is only when the bladder is greatly distended that action potentials appear in the afferent fibers of the hypogastric nerves.[13] Tonic contraction of the external sphincter is maintained by efferent impulses which pass along the pudic nerves. Bladder filling produces a sudden increase in the number of action potentials per unit time which reach the fundus and the bladder neck. When the intravesical pressure reaches a certain value, the detrusor muscle contracts (Barrington's first reflex) and the posterior third of the urethra relaxes (the sixth reflex). At the same time, the sudden absence of efferent discharges over the pudic nerves (central inhibition) results in the relaxation of the compressor urethrae muscle (the fifth reflex) and the bladder is effectively emptied.

TABLE CXXIV

THE BLADDER REFLEXES (FROM DATA PUBLISHED BY BARRINGTON[1-4])

REFLEX	EXCITING STIMULUS	AFFERENT ARM	EFFERENT ARM	RESPONSE	REFLEX CENTER
First	Distend bladder	Pelvic	Pelvic	Bladder contraction	Hind-brain
Second	Fluid through urethra	Pudic	Pelvic	Bladder contraction	Hind-brain
Third	Distend posterior urethra	Hypogastric	Hypogastric	Bladder contraction	Cord
Fourth	Fluid through urethra	Pudic	Pudic	Relax urethra	Cord
Fifth	Distend bladder	Pelvic	Pudic	Relax urethra	Cord
Sixth	Distend bladder	Pelvic	Pelvic	Relax posterior third of urethra	Cord

The act of micturition is facilitated by the passage of fluid through the urethra. This stimulus sets up impulses which enter the spinal cord over the pudic nerves[13] and reflexly produces contraction via the pelvic nerves (the second reflex) and relaxation of the urethra by way of the pudic nerves (the fourth reflex). Distention of the posterior urethra by high intravesical pressure is said to result in contraction of the detrusor muscle (third reflex). The afferent and efferent pathways are located in the hypogastric nerves. Doubt has been cast upon the existence of the third reflex, for in man dilatation of the posterior urethra produces no vesical contraction, nor is any sensation noted.[6] The bladder reflexes are of such a nature that vesical distention results in an orderly sequence of events.

Effects of Transection of the Spinal Cord.—If the bladder of a cat which has suffered transection of the spinal cord or medulla is distended by successive increments of fluid, the bladder contents are not suddenly and completely emptied.[1, 2] It is only when the intravesical pressure becomes sufficient to force open the urethra that fluid escapes, and then only in drops. As soon as the pressure falls below the threshold value, retention supervenes. One to two weeks after transection of the spinal cord the urethral resistance diminishes. When a large quantity of urine is present, its manual expression is facilitated if, after evacuating the bulk of it, the external pressure is removed for a few minutes. It is then found that the bladder which was previously lax has contracted and the remainder of the urine may be expressed easily. The reflex nature of this phenomenon is demonstrated by the fact that such a bladder contraction never occurs in cats which have lost the function of their sacral roots. The decrease in urethral resistance is associated with the escape of

urine from the urethra in rhythmic jets. While a series of such jets may amount to a considerable volume of urine, the fluid discharge always ceases before the bladder is emptied. If overdistention is allowed, hematuria occurs. It is of considerable interest to note that clinical reports of the state of the bladder following transverse cord sections in man closely parallel the descriptions of bladder activity in the spinal animal.[8]

The loss of bladder function shown by spinal animals must be related to the interruption of central pathways which extend high into the central nervous system. Barrington[2] has shown that the reflex arcs of the first and second reflexes are broken when the brain stem is sectioned at, or below, the mid-pontine region. Partial sections of the spinal cord at various levels indicate that centripetal and centrifugal paths lie in the dorsal half of the lateral columns near the periphery. Bilateral destruction of these small parts of the cord gives rise to the same disorganization of micturition as a complete spinal transection.[5] The reflex centers of the other four reflexes are located in the lower part of the spinal cord.

Effects of Lesions of the Peripheral Nerves: *The Pelvic Nerves.*—Bilateral division of the pelvic nerves in the cat results in urinary retention for several days.[1] In expressing urine from these bladders, it is necessary to maintain a constant steady pressure until the urethral resistance gives way. Even then, the bladder will not continue to empty if the pressure is decreased. It is impossible to empty the bladder completely in this way, for the laxity of the partially emptied viscus prevents the necessary pressure from being exerted upon the vesical contents. The giving way of urethral resistance is regarded as a reflex dilatation of the urethra (the fourth reflex). If the bladder is not emptied, it becomes overdistended and urine dribbles away. In time, the bladder distention leads to submucous hemorrhage, ulceration, and hematuria. Even in this condition the animal shows no signs of discomfort or bladder tenderness, suggesting that the pain of retention travels over the pelvic nerves. Two to twenty-nine days after operation, such cats deliberately select places for urination and squat to perform the act in the usual manner. The stream of urine is always feeble and only small quantities are voided. Although several acts of micturition may occur, posturinary palpation of the abdomen indicates that a considerable degree of retention is present. The bladder muscle of these animals shows considerable hypertrophy.[9]

The Pudic Nerves.—If the pudic nerves are cut in animals which have previously undergone pelvic nerve resection, urine drips away while the cat is walking about. When the bladder is squeezed, little or no urethral resistance is encountered. Voluntary acts of squatting to urinate no longer occur. It is evident that the integrity of the pudic nerves is necessary for the maintenance or for the inhibition of urethral tone as well as for the sensation which makes a cat with divided pelvic nerves conscious of the fact that it is about to pass urine. There are certain reasons for believing that in normal cats the impulses concerned with the desire to micturate are carried by the pelvic nerves.

Section of the pudic nerves in a normal cat results in a paralysis of the external sphincter which may lead to a slight degree of incontinence.[3] Similar injury in man is without any notable effect upon micturition.[10]

Division of the Sacral Posterior Roots.—In cats this produces symptoms quite analogous to those observed in patients with tabes dorsalis.[9] The operation

is constantly followed by a relaxed condition of the bladder which is more marked than that present after section of both pelvic nerves or after transection of the spinal cord.[1] Retention of urine is always present, and unless this is relieved, urine escapes in drops, but never in jets. Roentgenograms show that urine is constantly present in the posterior urethra. The "dead, persistent, powerful resistance" and the laxity of the bladder render complete emptying impossible. No improvement takes place during the subsequent life of the animal.

The Hypogastric Nerves.—In cats, section of the hypogastric nerves is followed by increased frequency of urination.[1] A transient frequency may be present after sympathetic nerve resection in man.[10] In neither species is the sympathetic innervation essential for micturition.

Bladder Sensations in Man.—The sensations of bladder filling, of painful distention, and the conscious perception of the desire to micturate are related to afferent impulses which are carried in the pelvic nerves.[10] And yet, the report that all of these sensations were experienced by a patient who had suffered complete lesions of the lower four sacral posterior roots indicates the sensory importance of the sympathetic pathway.[12] Further investigation has shown that, in man, the mechanical stimulation of the central end of a cut hypogastric nerve results in pain unless the spinal anesthesia extends above the ninth thoracic segment. In certain patients, vesical pain is said to be relieved by presacral nerve section.[10] A consideration of the sensory innervation of the bladder suggests that this operation must be expected to fail in many cases.[9]

The Cerebral Control of the Bladder.—Personal experience demonstrates that when the ordinary adult feels the urge to micturate, he can restrain the act until the proper opportunity for emptying the bladder presents itself. Voluntary restraint consists of the inhibition of vesical contractions, the closure of the external sphincter, and the contraction of the perineal muscles.[6] The internal sphincter, which is not under voluntary control, contracts and relaxes in reciprocal relationship with the detrusor muscle. When the intravesical pressure is sufficiently great, the "lifting" of voluntary restraint can evoke powerful contractions of the bladder. These may lead to reflex relaxation of the sphincters and bladder evacuation. While the external sphincter can be closed at will, its opening is reflexly produced by vesical contraction.[6]

It is generally conceded that the absence of inhibitory control shown by the infant bladder is related to the lack of cortical development. This conception is supported by the observation that certain lesions of the suprasegmental parts of the central nervous system produce a bladder which is functionally identical with that of the baby.

Experimental studies indicate that the cerebral cortex of animals exerts some control over bladder function. In the normal cat, the quantity of urine passed at each act varies greatly. Following cortical extirpation, the volume of fluid passed at each micturition becomes much more constant.[14] This observation suggests that the cerebral cortex modifies the reflex threshold concerned with the act of micturition.

thrombin formation, 319
thromboplastic factor from lung, 315
time, 329, 330
trypsin or papain activity on prothrombin, 316, 318
vitamin K and bile salts, 317
and prothrombin, 316
color index and, 305
of skin and, 451
volume index in, 306
composition of, 296, 297
in cyanosis, 685, 687
renal regulation of, 1093
concentration of, in exercise, 1086
differential distribution of, 470
effect of pH on oxygen content, 633
electrolyte content and sea water, 295
fat, 809
fetal, alkali deficit in, 673
flow, arterial, measurement of, in a limb, 435
respiratory variations in, 499
retrograde, 432
incisura and, 433
velocity of, 431, 434
determined by stromuhr, 432
cardiac index and, 412
cerebral, 512
coronary, 507
regulation of, 510
hepatic, 503
measurement of, in peripheral vessels, 432
peripheral resistance to, 408
portal, 503
renal, measured by clearance method, 1121
size of exit vessels and, 410
submaxillary gland, 1078
through active muscles, 859
urine formation and, 1104
venous, 453
muscles and, 454
respiratory effects on, 455
viscosity and, 408
function of, 295
gas content of, 614
gas tensions in, 615
glucose, adrenalin and, 170
groups, 303
anthropological aspects, 304
heredity and medicolegal aspects, 304
Jansky classification of, 304
Moss classification of, 304
nomenclature, 304
technical methods, 303
hemoglobin concentration in, 304
content of, 296
homeostasis and, 296
mixed venous, oxygen and CO_2 content of, 627
oxygen, and CO_2 tension, effect on hemoglobin, 633

Blood oxygen—Cont'd
capacity of, 296
dissociation curves in, 632
oxygenation of hemoglobin and acidity, 639
"pendulum," 393
plasma, 312 (*see* Plasma)
acacia and, 312
formation of albumins, 312
of fibrinogen, 312
of globulin, 312
osmotic force of protein, 311
proteins and viscosity of, 311
relation to lymph and tissue fluid, 487
pressure, arterial, adrenalectomy and, 1011
after section of buffer nerves, 468
age changes in, 424
anacrotic and catacrotic waves in, 426
at varying distances from heart, 427
auscultation, 420
cardiac output and, 414
changes with apnea and hyperpnea, 580
coronary, 506
diastolic, 411
effect of work upon, 858
elasticity coefficient and, 435
end and lateral, 418
exercise and, 855, 858
factors influencing in man, 414
"formo-oscillatorisch" criteria, 422
gravity and, 429

in posterior roots, 438
nerve erigentes as, 439
to salivary glands, tongue and larynx, 439
fibers, accommodation and, 50
classified, 47
myelinated, 47
unmyelinated, 47
velocity of propagation as a basis of classification, 49
glycogen and, 57
heat production of, 54
and oxygen usage in, 55
impulse, 40
impulse frequencies in, 46
independent excitability in, 41
initial heat of impulse, 54
iodoacetate poisoning and, 58
isolated conduction in, 40
lactic acid and, 57
law of specific properties of, 68
local currents in, 51
local excitatory state in, 41, 42
magnitude of conduction in, 46
mechanism of propagation in, 50
membrane capacity of, 52
hypothesis and, 50
potential of, 51
myelin sheath of, 47
modes of Ranvier of, 47
net, 3
as a syncytium, 4
conduction in, 3
rate of conduction in, 3
peripheral, sensory and motor signs in caisson disease, 695, 698
phosphocreatine breakdown in, 57, 58
potassium ions and potential, 45
and excitability, 49
potential at injured points in, 47
potential, cell membrane and, 45
pressure block in, 75
refractory period of, 45
absolutely refractory period of, 45
relatively refractory period of, 45
subnormal conduction velocity with, 46
regeneration of, 5
respiration of, 56
resting respiratory quotient of, 56
spike or spike potential of, 43
splanchnic, 167
stimuli and, 41
stimulus rate and heat production in, 55
subnormal excitability in, 46
velocity of conduction in, 46
summation of stimuli and, 41
Nerve—Cont'd
supernormal excitability in, 46
threshold stimulus of, 41
velocity of conduction, measurement, 42
Nervi erigentes, 172 (*see* Pelvic nerves)
as vasodilators, 439
Nervous control of salivary glands, 892
Nervous system (*see* Central nervous system)
Neural control, in fat metabolism, 814
lobe of pituitary gland, 1019
Neuroblast, 4
Neurohumeral control of water balance, 197
Neurohypophysis, 188, 189, 1017 (*see* Pituitary gland)
Neuroid transmission, 3
Neuromuscular and central nervous system, 1
irritability, parathyroid deficiency and, 1004
mechanisms, evolution of, 1
in unicellular organisms, 1
primitive, 1
responses, unit of, 78
Neuromyal junction, 8, 59
acetylcholine and, 61
and synapse, 59
cell membrane and, 60
cholinecterase and, 61
curare and, 59
electrical theory and, 60
end-plate delay and, 59
heterochronism and, 60
isochronism and, 60
motor end organs or plates and, 59
polarity and, 59
potassium ions and, 64
stages of conduction, 63
sympathin and, 61
transmission, chemical theory of, 61
Neuron, 4
as anatomical unit, 5
as functional unit, 6
as genetic unit, 4
as trophic unit, 5
chromatolysis of, 5
cortical potentials and, 211
internuncial depression of, in spinal shock, 88
role in central synaptic delay, 97, 98
internuncial or associational, 7 (*see* Internuncial neuron)
pool, convergence in, 108
fractionation of, 108
occlusion in, 109
reflex arc and, 98
Neurons, central, excitability changes in, 100
internuncial, acting on ocular motor neurons, 105
after discharge and, 107
after discharge in, 103
changes in, with inhibition, 114
closed chains of, 106
facilitation, 103, 106
multiple or open chain in, 106
potentials in, 104
role of, in central conduction, 102
subnormality and inhibition in, 114
sustained excitation in, 105, 106

Neurons—Cont'd
motor, discharge in, and depth of respiration and, 558
optimal excitability in respiratory center, 606
postganglionic, 115
resting period of, 573
Neurosis, resemblance of, in anoxia, 684
Nickel in animal nutrition, 840
Nicotine, action on respiration, 592
sympathetic ganglia and, 166
synaptic transmission in ganglia and, 119
Nicotinic acid, pellagra-preventive, 824, 825
Nictitating membrane, tonic activity in sympathetic and, 169
denervated as an indicator for sympathin, 180
hypothalamic stimulation and, 192
of cat, sympathetic transmission and, 120
Nidation, 1041, 1049
Night blindness, vitamin deficiency and, 820
Ninth cranial nerve, parasympathetic nervous system and, 172
nerve (glossopharyngeal) afferents in vasomotor reflexes, 458
secretion of saliva and, 174
Nitrites, effect on cerebral vessels, 512
Nitrogen, diffusion through cell membranes, 696
embolization in caisson disease, 695, 696
equilibrium, foods necessary for, 791
protein metabolism and, 790
metabolism, thyroid hormone and, 997
solubility in fat, 696
Nodes of Ranvier, 47
Noma, starvation and, 835
Normal standing, suprabulbar mechanisms and, 138
No-threshold substances, renal function and, 1103
Noxious stimuli, dominance of, 77
pain and, 73
Nucleases, of intestinal juice, 974
Nucleic acid, catabolism of, 806
disintegration in intestine, 974
Nucleoproteins, 805
Nucleotides, pyridine, 715
Nucleus (*see* under specific name)
Nucleus interpositus, 153
Nussbaum preparation, 1114
Nutrition, 831
caloric requirements, 831
fat requirements, 832
food requirements, 831
inorganic salts in, 831
metabolism and, 720
protein requirements, 831
sodium and potassium in, 837
thyroid gland and, 996
Nyctalopic, vitamin A deficiency and, 820
Nymphomania, 1044
Nystagmus, cerebellum and, 155
eye movements, labyrinthine reflex and, 145
postrotatory, 145, 280
stimulation of semicircular canals and, 145
rotatory, 280
with color blindness, 277

O

Obesity, and nutrition, 835
hypothalamus and pituitary and, 199
plasma volume and, 1070
Occlusion, in reflex arc, 108
in sympathetic ganglia, 116
Ocular motor neurons, duration of transmission at synapses, 122
internuncials acting on, 105
second phase of summation in, 121
spatial summation at, 122
Oculomotor nerve stimulation produces nearsightedness, 251
nucleus, excitation of synaptic knobs of, 99
Odors, classification of, 292
Oestrone, 1043
Olfaction, 291
decorticate animal and, 92
neocortex and, 214
Olfactory and gustatory areas, 214
bulb, hypothalamus and, 187
chamber, 291
coefficient, 291
and boiling point, 292
epithelium, 291
fatigue, relation to brain tumors, 292
nerve, area innervated by, 291
receptors, character of, 291
solid, 292
Olfacto-visceral center, hypothalamus and, 187
Oligemia, hemorrhage and, 518
relative, 516, 518
sweating and, 518
through fluid loss, 523
vomiting and, 518
Oligocythemia, 516
Operative myxedema, 1000
Ophthalmoscope, 258
Opisthotonus, 154
following cerebellar injury, 159
Optic chiasm, 215
nerve, number of fibers in, 262
tract, thalamus and, 201
tracts, lesions in, 215
Optical system of eye, 251
Organ of Corti, 287
Organ weight in relation to body weight, 1060
Organization of the mammalian central nervous system, 82
Orophysin, 1032
Orthopnea, 543, 650
Oscillatory criteria in blood pressure, 421
Oscillograph, cathode ray, 24, 41
Osmotic balance in capillaries, 447, 1085
in lung, 495
disturbances of, 495
force of blood protein, 311
pressure, concentration of water and, 1084
effective in capillaries, 448
in liver capillaries, 503
in shock and, 530

Osmotic pressure—Cont'd
of aqueous humor, 261
in brain, 514
water exchange and, 1084
Ossicles, auditory, 284
vibrations of, 284, 285
Osteitis fibrosa cystica, in hyperparathyroidism, 1006
Osteomalacia, from lack of vitamins, 835
Osteoporosis in hyperparathyroidism, 1006
Otolith organs as proprioceptors, 66
Otoliths, 143
labyrinthine righting reactions and, 139
Output, cardiac variations in, 388
Oval window, 283
Ovarian deficiency, 1040
hormone, 1042
in menopause, 1052
Overheating, hypothalamic injury in, 195
Overlap, sympathetic ganglia and, 115
Ovulation, 1047
hypothalamus and, 199
Oxidase, 713
cytochrome, 714
Oxidation, cyclic processes, 712
definition, 712
Oxygen administration, methods and principles, 702
Oxygen, alveolar tension and atmosphere, 622
coefficient of utilization, 708
combination with hemoglobin, 630
consumption at rest, 614
diastolic volume of heart and, 395
following adrenalectomy, 1011
foods in relation to, 733
in skeletal muscle, 772
of beating heart, 784
pituitary extract and, 1021
work and, 842
debt, during exercise, 843
diffusion rate in lung, 621
variation in, 623
dissociation curves in blood, 633
heat production in nerve and, 55
in fetal blood, 673
in inspired air, effect on respiratory center, 565
inhalation at high altitude, 610
lack (*see* Anoxemia)
limitations of, in aviation, 703
maximum usage of, 621
mechanisms for utilization by muscle, 774
percentage in air, 614
poisoning, 704
requirements for running, 843
secretion of, 690
secretion of, in lungs, 622
supply to tissues, 707
tension at high altitude, 689
in air, 615
in blood, relationship to CO_2 tension, 631
in tissues, 629, 707, 708
therapeutic value of, 699
in angina pectoris, 700
in carbon monoxide poisoning, 700
Oxygen, therapeutic value of—Cont'd
in cardiac decompensation, 700
in pulmonary condition, 700
usage, smooth muscle and, 37
utilization, by cardiac muscle, 785
during exercise, 853
velocity of combination with hemoglobin, 635
Oxytocic activity of postpituitary extract, 1021

P

Pacemaker, 349 (*see* Heart)
Pacinian corpuscles as vascular receptors, 460
Pain, 73
adrenalin secretion and, 170
chordotomy and, 206
cortical stimulation and, 207
effect on respiration, 600
fiber size and, 73, 74
fibers, 73, 74
free nerve terminations and, 65
frequency of stimulation and, 73, 74
localization of, 70
nociceptive stimuli and, 73
referred, 70
sense organs of, in cornea, 278
specific fibers, 74
pathways, 74
spots, 71
thalamus and, 204
threshold of, 73
Paleocerebellum, 152
Paleocortex, 214
Paleostriatum, 227 (*see also* Ganglia, basal)
Paleothalamus, 202
Pallidum, 227 (*see* Ganglia, basal)
Pancreas, hormone of, 1058
islets of Langerhans, 759
Pancreas-adrenal relationship, 1014
Pancreatic acini, 889
diabetes, 759
adrenals and, 1014
glycogen and, 759
hypophysectomy and, 770
insulin and, 762
digestion, 972
milk and, 974
proteins in, 973
sucrose and, 974
juice, acidity of, 972
amylase of, 974
enzyme content of, 897
erepsin of, 973
fasting, 914
lactase of, 974
lipase of, 973
sucrase of, 974
trypsin of, 972
secretion, achlorhydria and, 913
acid chyme and, 913
atropine and, 897
bile salts and, 913
hormone control of, 895

Pancreatic secretion—Cont'd
nervous and hormone control, comparison, 898
nervous control of, 896
secretin stimulation of, 895
vagus stimulation of, 897
variations in, 913
Pancreatin, 972
therapeutic administration of, 973
Panting, hypothalamus and, 196
in temperature regulation, 196, 863, 871, 881
water loss and, 1073
Pantothenic acid, 825
Papain, blood coagulation and, 316, 318
Papillary muscles, 343
Paralytic secretion, 894, 1077
Paramecium, neuromuscular responses of, 2
Paraplegia-in-extension, 227
Paraplegia-in-flexion, 227
Parasympathetic division of autonomic system, 172
Parasympathetic nervous system, acetylcholine and, 178
atropine and, 178
chemical mediation in, 177
cholinergic fibers and, 182
vasoconstrictors to coronary arteries, 438
cholinesterase and, 178
chordotympanic nerve and, 178
constriction of coronary arteries, 511
cranial outflow of, 172
defecation and, 174, 949
defined, 166
Edinger-Westphal nucleus and, 184
eserine and, 178
gastrointestinal tract and, 174, 934, 945, 949
hyperactivity in oxygen poisoning, 704
hypothalamus and, 193
mediator of postganglionic impulses, 178
micturition and, 174, 1127
nervi erigentes and, 172, 1127
protective function of, 174
pupils and, 174
restricted distribution of, 174
sacral outflow of, 172
salivatory nuclei and, 184
seventh nerve and, 172
temperature regulation and, 196
third nerve and, 172
vagal nuclei and, 184
vasodilation and, 175
vasodilatory fibers in, 439
vasodilatory fibers to genitals and, 175
Parathyreotropic factor in anterior pituitary, 1031
Parathyroid deficiency, 1004
glands, 1003
acid base balance and, 1004
extracts of, 1005
functional significance of, 1003
Parathyroid glands—Cont'd
hyperactivity of, 1006
thyroid and, 1004
hormone, vitamin D and, 1005
secretion, control of, 1005
tetany, calcium metabolism and, 1005
Paraventricular nucleus, 189 (*see* Hypothalamus)
capillary bed of, 190
Paresthesias, cortical lesions and, 207
thalamus and, 204, 205
Parkinsonism, 230
Parolfactory region, 187
Parotid gland, histological signs of secretion in, 888, 889
zymogen granules, 888
Pars intermedia (*see* Pituitary gland)
Particulate matter, lymphatic permeability and, 489
Parturition, intrapulmonary pressure in, 542
Past experience, cerebral cortex and, 218
Past pointing, 147
Pause, compensatory in heart, 344
Pellagra-preventing vitamin, 821
Pelvic nerves (nervi erigentes), 172
general functions of, 174
urinary bladder and, 1127, 1128, 1130
Pelvirectal flexure, 947
Pepsin, action of, 970
combination with protein, 970
destroyed in intestine, 971
hydrochloric acid and, 970
origin of, 969
precursor of, 969
protein nature of, 970
Pepsinogen, 969
Peptic digestion, 970, 971
products of, 970
Perceptive deafness, 290
Pericardium, importance of, 398
Perilymph, 143
Perimeter, 267
Perimetry, 267, 268
Period of contraction of muscle, 15, 16
of filling of heart, 378, 379
of relaxation of muscle, 15, 16
Peripheral ganglia, autonomic nervous system and, 165
neuritis, 821
resistance, 338, 339, 410
vascular disease, 481
Peristalsis, defecation and, 951
esophageal, 924
gastric, 932
hunger contractions and, 958
intestinal obstruction and, 947
neurogenic origin of, 945
reversed intestinal segment and, 946
small intestine and, 944, 946
Peritoneum, absorption from, 985
Periventricular system of fibers, 191
Permeability, glomerular, 1106
of capillaries, 449, 488
of lymphatics, 489

Perspiration, insensible, 870, 1073
pH (*see also* Hydrion)
changes, vasomotor responses and, 476
of fetal blood, 673
Phagocytosis, 310, 311
Pharyngeal orifice, occlusion in relation to middle ear, 286
Phenobarbital, respiratory reflexes and, 594
Phenol red, renal function and, 1102, 1105, 1115, 1116, 1117
Phlorizin, effect on aglomerular kidney, 1116
glycosuria, 1113
renal studies with, 1113
Phonoreceptors, 65
Phosphate compounds and carbohydrate changes in muscle contraction, 778
metabolism in muscular contraction, 778
Phosphates, role in blood reaction, 644
Phosphocreatine breakdown in nerve, 57, 58
content of mammalian muscle, 779
in muscular contraction, 778
salivary gland metabolism and, 891
Phosphoglycerate in glycolysis, 781
Phospholipids in fat transport, 809
Phosphorus in animal nutrition, 839
vitamin D and, 826
Photoelectric currents of excised frog's eye, 264
Photoreceptors, 65
Physical aspects of muscular contraction, 29
control of body temperature, 865
Physiologic changes during fasting, 834
anticoagulant, 324
Picrotoxin, dyspnea and, 651
effect in respiratory failure, 667, 671
Pillar response in limbs, 125
Pilleus ventriculi, 931
Pineal gland, 1055
Pinealectomy, 1056
Pinna, function of, 283
Pitch, 237
analysis by inner ear, 288
as conditioning stimulus, 234
differences in, 288
Pitocin, 1021
Pitot's tubes, 433
Pitressin, effect on capillaries, 450
vasoconstrictor action, 443, 1021
water balance and, 1021, 1088
Pituicytes, 1017
Pituitary basophilism, 1015
gland, adiposity and, 199
anatomical description of, 189, 1017
anterior lobe, acidophiles of, 1017
acromegaly and, 1022, 1023
adrenotropic factor of, 1014, 1031
basophiles of, 1017
blood sugar reserve, principle of, 1032
carbohydrate metabolism and, 766
castration and, 1045
cells of, 1017
chromophiles of, 1017
chromophobes of, 1017
diabetes insipidus and, 1020, 1125
mellitus and, 767
Pituitary gland, anterior lobe—Cont'd
diuretic hormone of, 1020, 1124, 1125
dwarfism and, 1024
extirpation of, 1024, 1027, 1031, 1032
extracts, diabetes mellitus produced by, 767
effect in adrenal deficiency of, 1014
effect on protein metabolism of, 1024
effect on thyroid, 1030, 1032
gonadotropic factors in, 199, 1028
growth factor in, 1022
ketogenic factor in, 1032
lactogenic factor in, 1029
maternal instinct and, 1030
fat metabolism and, 1031
follicle stimulative factor of, 1028
gametokinetic hormone of, 1028
gigantism and, 1022
gonadotropic effects of, 198, 1026, 1027, 1046
growth-promotive hormone of, 1022, 1023, 1024
Houssay animal and, 767
implantation of, 1025, 1027, 1045
ketogenic principle of, 1032
lactogenic factor of, 1029
luteinizing factor of, 1027
number of hormones of, 1033
obesity and, 1025
parathyreotropic factor of, 1006, 1031
polyuria and, 1020, 1125
protein metabolism and, 1024
sexual infantilism and removal of, 1027
somatotropic hormone of, 1023
sterility in women and, 1054
testis and, 1045
thyreotropic factor of, 1001, 1031
antidiuretic principle and, 197, 1020, 1124
blood pressure and, 475
supply of, 199, 1018
carbohydrate metabolism and, 766
components of, 189, 1017
derivation of, 188, 1017
development of, 189
divisions and subdivisions, 189, 1017
glandular lobe, 189
gonads and, 198, 1026
hypothalamic control of, 197
hypothalamus and, 188, 1019
median eminence and, 189, 192, 198
nerve supply of, 192, 199, 1018, 1020
ovulation and, 199, 1018
water balance and, 197, 1020, 1125
neural lobe, 189, 1017, 1019
antidiuretic hormone and, 198, 1020
atrophy of after stalk transection, 192, 1020
innervation of, 192
water balance and, 198
overgrowth and, 1017
pancreatic diabetes and, 766
pars distalis (*see* Anterior lobe)
pars intermedia, 189, 1017, 1019
cells of, 1017

Pituitary gland, pars intermedia—Cont'd
intermedin and, 1022
melanophores and, 1022
pars tuberalis, 189
arrangement of, 1017
cells of, 1017
discordant results and, 1019
posterior lobe, 189, 1019
cells of, 1017
diabetes insipidus and, 197, 1020, 1124
extracts, antidiuretic action of, 197, 1020, 1021, 1124
blood pressure and, 1021
diuretic action of, 1124
effects on uterus of, 1020, 1021
fractions of, 1021
oxygen consumption and, 1021
oxytocic effect of, 1020, 1021
pressor effect of, 1021
pulse rate and, 1021
renal action of, 1125
water intoxication and, 1082
functions of, 1022
polyuria and, 197, 1020, 1124
renal excretion of water and, 1124
water exchange and, 1083
protein metabolism and, 807
Simmonds' disease and, 1025
testes and, 1045
thyroid and, 770, 1001, 1031
vagal stimulation and, 475
vasomotor reflexes and, 475
water balance and, 197
stalk, 189
nerve fibers in, 192, 199, 1018, 1020, 1125
ovulation and, 199
section of, 198, 199
Pituitrin, antidiuretic action of, 197, 1124
injection into cerebral ventricles, 193
pulmonary vessels and, 496
secretion of, hypothalamus and, 193
water balance and, 1088
Placenta, gonadotropic principles derived from, 1028
Placing reactions, analysis of, 143
contralateral control and, 142
description of, 140
exteroceptive stimuli and, 140
in monkey, 142
proprioceptive stimuli and, 140
sensory cortex and, 208
visual cortex and, 140
Plasma clearance, analysis of renal function by, 1117
method of determining, 1118
compared with urine, 1102, 1103
compartment, 1064, 1065
composition, kidney and, 1093
effective osmotic pressure of, 448, 1085
lipids in, 809
proteins, albumin and globulin, 447
blood volume and, 517
edema and, 447
osmotic pressure of, 335, 447, 488, 494, 1085, 1108
Plasma—Cont'd
ultrafiltrate, glomerular filtrate and, 1105
volume, age and, 1070
calculated from plasma protein, 1064
capillary fluid exchange and, 1067
constancy of, 1067
determined by diffusible foreign substances, 1067
by vital dyes, 1067
with T-1824, 1064
erroneous estimation of, 1064, 1068
inconstancy of, 1070
individual variations in, 1070
normal values, 1070
obesity and, 1070
reduction in muscular exercise, 1086, 1087
thirst and, 1079
vasoconstriction and, 1088
water diuresis and, 1123
Plastic quality of decerebrate rigidity, 134
Plasticity of smooth muscle, 38
Platelet stability, 327
Platelets, 315 (*see* Blood coagulation)
Plethora, 529
definition of, 516
hydremic, 530
